Preface

High-throughput screening (HTS) methodologies for lead identification in drug discovery were developed in the 1980s to enable the utilization of advances in genomics and combinatorial chemistry. Since their advent, HTS methodologies have developed rapidly and have been widely adopted in the pharmaceutical industry. Consequently, the number of potential drug candidates identified by HTS has steadily increased over the past two decades. The HTS approach tends to identify leads with high-molecular weight and lipophilicity, and, consequently, poor water solubility. As more and more leads are identified by HTS, poorly water-soluble drug candidates are emerging from drug discovery with greater frequency. The problem of poor solubility has therefore become pervasive in the pharmaceutical industry recently, with percentages of poorly water-soluble compounds in development pipelines reaching as high as 80–90% depending on the therapeutic area.

Drug dissolution is a necessary step to achieve systemic exposure that ultimately leads to binding at the biological target to elicit the therapeutic effect. Poor water solubility hinders dissolution and therefore limits drug concentration at the target site, often to an extent that the therapeutic effect is not achieved. This can be overcome by increasing the dose; however, it may also lead to highly variable absorption that can be detrimental to the safety and efficacy profile of the treatment. In these cases, solubility enhancement is required to improve exposure, reduce variability, and, ultimately, improve the drug therapy. It is therefore understood that in modern pharmaceutical development, solubility-enhancement technologies are becoming critical to rendering viable medicines from the growing number of insoluble drug candidates.

A pharmaceutical scientist's approach toward solubility enhancement of a poorly water-soluble molecule typically includes detailed characterization of the compounds physicochemical properties, solid-state modifications, advanced formulation design, nonconventional process technologies, advanced analytical characterization, and specialized product performance analysis techniques. The scientist must also be aware of the unique regulatory considerations pertaining to the nonconventional approaches often utilized for poorly water-soluble drugs. One faced with the challenge of developing a drug product from a poorly soluble compound must possess at minimum a working knowledge of each of the above-mentioned facets and

detailed knowledge of most. In light of the magnitude of the growing solubility problem to drug development, this is a significant burden especially when considering that knowledge in most of these areas is relatively new and continues to develop. There are numerous literature resources available to pharmaceutical scientists to educate and provide guidance toward formulations development with poorly water-soluble drugs; however, a single, comprehensive reference is lacking. Furthermore, without access to a vast journal library, the detailed methods used to implement these approaches are not available. The objective of this book is therefore to consolidate within a single text the most current knowledge, practical methods, and regulatory considerations pertaining to formulations development with poorly water-soluble molecules.

The volume begins with an analysis of the various challenges faced in the delivery of poorly water-soluble molecules according to the route of administration, i.e., oral, parenteral, pulmonary, etc. This chapter provides understanding of the formulation strategies that one should employ depending on the intended route of administration. Chapter 2 covers analytical techniques most pertinent to poorly water-soluble drugs with regard to preformulation, formulation characterization, and in vitro performance assessment. Solid-state approaches to overcoming solubility limitations are discussed in Chapter 3. This chapter presents an in-depth review of the solubility benefits obtained via conversion of drug crystals to salts, cocrystals, metastable polymorphs, and amorphous forms. When such solid-state approaches are not viable, particle-size reduction of the stable crystalline form is perhaps the next most straightforward option. In Chapter 4, mechanical particle-size reduction technologies are described, providing a comprehensive discussion of traditional and advanced milling techniques commonly used to increase surface area and improve dissolution rates.

Oftentimes, modification of the API form is not possible and particle-size reduction fails to appreciably increase the dissolution rate owing to the inherent solubility limitation of the stable crystalline polymorph. In these cases, a noncrystalline approach is necessary; perhaps the most straightforward noncrystalline approach is a solution-based formulation. Solution-based approaches are covered by Chapters 5–7 where liquid formulation technologies for poorly water-soluble drugs are presented. Chapter 5 provides a review of solution systems for oral delivery whereby the molecule is dissolved in a suitable nonaqueous vehicle. The chapter discusses the various vehicles available for such systems as well as options for conversion to a final dosage form. Chapter 6 reviews techniques for overcoming compound solubility challenges in developing liquid formulations for parenteral administration, which is of particular relevance as the number and complexity of cancer therapeutics continue to increase. Advanced liquid formulations for oral delivery, self-emulsifying systems, are discussed in Chapter 7. These systems are advancements over traditional solution formulations in that the formulation droplet size formed on contact with GI fluids can be controlled through rational formulation design. Controlling droplet size to the micro- or nanometer scales has been shown to produce significant enhancements in drug absorption.

In many cases, poorly water-soluble compounds also exhibit limited solubility in vehicles suitable for oral liquid formulations. In these cases (assuming all other previously mentioned options are not viable), an amorphous formulation approach is often necessary. The design of amorphous formulations presents numerous challenges, which much of the latter half of this book (Chapters 8–12) aims to address. These chapters describe the importance of appropriate preformulation studies, formulation design, process selection, as well as considerations specific to the selected process technology. In Chapter 8, a structured, rational approach toward the development of optimized amorphous solid dispersion formulations is presented. Specific emphasis is given to critical preformulation studies, identification of the best excipient carrier system, optimization of drug loading, and process technology selection. Chapter 9 provides a comprehensive guide to the application of hot-melt extrusion technology for the formulation of poorly water-soluble drugs. This chapter provides a detailed overview of the process technology as well as formulation design considerations specific to hot-melt extrusion applications. Spray drying is the subject of Chapter 10, again emphasizing the process technology and formulation development specific to spray drying. Particular focus is given to the development of amorphous spray-dried dispersions owing to its industrial relevance to the production of viable products containing poorly water-soluble drugs. Chapter 11 teaches cryogenic technologies whereby nanostructured particles and amorphous solid dispersions are formed by rapid freezing technologies. The chapter discusses different cryogenic process technologies, formulation design considerations, and downstream processing options. Precipitation technologies for the production of engineered particles and solid dispersions are covered in Chapter 12. Various solvent/antisolvent techniques are discussed along with formulation design principles, particle recovery techniques, and key process design considerations.

Emerging technologies relevant to the formulation of poorly water-soluble drugs are discussed in Chapter 13. These are technologies that have begun to appear in the literature and elsewhere in recent years that exhibit promise, but have yet to mature. Finally, in Chapter 14 regulatory considerations specific to drug products of poorly water-soluble compounds are presented. It is the aim of this chapter to educate formulation scientists regarding unique regulatory aspects to consider for solubility-enhancement approaches, i.e., solid-state modifications, particle-size reduction, lipid/solution formulations, and amorphous solid dispersions. This chapter also provides a unique review of case studies for marketed products that employ these solubility-enhancement approaches, highlighting the principal regulatory concerns for each case.

This volume is intended to provide the reader with a breadth of understanding regarding the many challenges faced with the formulation of poorly water-soluble drugs as well as in-depth knowledge in the critical areas of development with these compounds. Further, this book is designed to provide practical guidance for overcoming formulation challenges toward the end goal of improving drug therapies with poorly water-soluble drugs. Enhancing solubility via formulation intervention is a unique opportunity in which formulation scientists can enable drug therapies by creating viable medicines from seemingly undeliverable molecules. With the ever-increasing number of poorly water-soluble compounds entering development,

the role of the formulation scientist is growing in importance. Also, knowledge of the advanced analytical, formulation, and process technologies as well as specific regulatory considerations related to the formulation of these compounds is increasing in value. Ideally, this book will serve as a useful tool in the education of current and future generations of scientists, and in this context contribute toward providing patients with new and better medicines.

The editors sincerely thank all contributors for their dedication toward achieving the vision of this book. It is thanks only to your knowledge and efforts that it was accomplished.

Chapter 1

Route-Specific Challenges in the Delivery of Poorly Water-Soluble Drugs

Stephanie Bosselmann and Robert O. Williams III

Abstract Poor aqueous solubility of new chemical entities presents various challenges in the development of effective drug-delivery systems for various delivery routes. Poorly soluble drugs that are delivered orally commonly result in low bioavailability and are subject to considerable food effects. In addition, poorly soluble drugs intended for parenteral delivery generally have to be solubilized with large amounts of cosolvents and surfactants, oftentimes resulting in adverse physiological reactions. Finally, successful formulation design of poorly soluble drugs intended for pulmonary administration is mainly hindered by the limited number of excipients generally recognized as safe for this route of delivery. In summary, this chapter reviews the specific challenges faced in the delivery of poorly water-soluble drugs via oral, parenteral, and pulmonary administration.

1.1 Introduction

Adequate aqueous solubility of new chemical entities (NCEs) is one of the key properties required for successful pharmaceutical formulation development. Solubility is generally defined as the concentration of the compound in a solution which is in contact with an excess amount of the solid compound when the concentration and the solid form do not change over time (Sugano et al. 2007). Solubility is closely related to dissolution which is a kinetic process that involves the detachment of drug molecules from the solid surface and subsequent diffusion across the diffusion layer surrounding the solid surface. The relationship of solubility and dissolution rate is described by the Nernst–Brunner/Noyes–Whitney equation:

e-mail: williro@mail.utexas.edu

$$\frac{dM}{dt} = \frac{D \cdot A}{h} (c_s - c_t),$$

where dM/dt is the dissolution rate, D the diffusion coefficient, A the surface area, h the diffusion layer thickness, c_s the saturation solubility of the drug in the bulk medium, and c_t the amount of drug in solution at time t (Noyes and Whitney 1897; Nernst 1904). The use of high-throughput screening and combinatorial chemistry for the development of NCEs has resulted in an increasingly number of compounds that are characterized by low aqueous solubility (Lipinski 2000). From the Nernst–Brunner/Noyes–Whitney equation, it is evident that compounds characterized by low solubility (c_s) will only establish a small concentration gradient ($c_s - c_t$), resulting in low dissolution rates. This, in turn, causes many problems *in vivo* when poorly soluble drugs are administered via various routes of administration. Poorly soluble drugs that are delivered orally commonly result in low bioavailability and high intersubject variability. Additionally, poorly soluble compounds are known to have a higher predisposition for interaction with food resulting in high fast/fed variability (Gu et al. 2007). In order to make low solubility drugs available for intravenous administration, they generally have to be solubilized employing large amounts of cosolvents and surfactants. Problems often arise from the fact that these excipients are not very well tolerated, potentially causing hemolysis and/or hypersensitivity reactions (Yalkowsky et al. 1998). In addition, there is the risk of drug precipitation upon injection and subsequent dilution of the solubilized formulation. Finally, successful formulation design of poorly soluble drugs intended for pulmonary administration is mainly hindered by the limited number of excipients generally recognized as safe for this route of delivery. This chapter reviews the specific challenges faced in the delivery of poorly water-soluble drugs for oral, parenteral, and pulmonary delivery.

1.2 Oral Route of Administration

In spite of significant advances in other areas of drug delivery such as pulmonary or topical, oral drug delivery still remains the most favored route of administration. Not only are oral drug products conveniently and painlessly administered resulting in high acceptability, they can also be produced in a wide variety of dosage forms at comparably low costs, making them attractive for patients and pharmaceutical companies alike (Sastry et al. 2000; Gabor et al. 2010). In theory, the unique physiology of the gastrointestinal (GI) tract with its high intestinal surface area and rich mucosal vasculature offers the potential for excellent drug absorption and accordingly high bioavailability (Lee and Yang 2001). Still, oral bioavailability is often low and variable as the process of drug absorption from the GI tract is far more complex and influenced by physiological factors such as GI motility, pH, efflux transporters, and presystemic metabolism; extrinsic factors such as food intake and formulation design; and most essentially the physicochemical properties of the drug (Levine 1970; Martinez and Amidon 2002).

Following oral administration of a solid dosage form, the drug must first dissolve in the GI fluids and then be absorbed across the intestinal mucosa to reach the systemic circulation and exert its pharmacological effect. Accordingly, the key properties of potential drug candidates defining the extent of oral bioavailability and thus being vital for successful oral product development include aqueous solubility and intestinal permeability. Based on these two crucial parameters, the Biopharmaceutics Classification System (BCS) assigns drugs to one of four categories: high solubility, high permeability (BCS I); low solubility, high permeability (BCS II); high solubility, low permeability (BCS III); and low solubility and low permeability (BCS IV) (Amidon et al. 1995).

Ideally, an NCE is characterized by high aqueous solubility and permeability (BCS I); yet, only about 5% of NCEs fulfill this requirement, while approximately 90% of NCEs are considered poorly soluble in combination with either high or low permeability (BCS II and IV) (Benet et al. 2006). Due to the combination of low permeability and low solubility, BCS IV compounds are generally troublesome drug candidates and, therefore, rarely developed and marketed. BCS II compounds are usually more promising candidates since permeability through the GI mucosa is not a problem. Nevertheless, intestinal absorption is solubility/dissolution rate-limited, oftentimes resulting in low and erratic oral bioavailability.

Overall, problems associated with poorly soluble compounds not only revolve around low oral bioavailability but also involve high susceptibility to factors such as food and metabolism as discussed in more detail in the following sections.

1.2.1 Challenges in Oral Delivery of Poorly Water-Soluble Drugs

Coadministration of oral dosage forms with meals generally results in one of three scenarios: (1) the extent of absorption decreases which is referred to as a negative food effect; (2) the extent of absorption increases corresponding to a positive food effect; and (3) no substantial change in the extent of absorption takes place (Welling 1996). Given the fact that food intake commonly translates into universal physiological actions, predictions of what scenario will take place may be made based on the physicochemical properties of the drug (Gu et al. 2007). For instance, Fleisher et al. estimated the effect of food on the extent of drug absorption based on the characteristics of the drug as classified by the BCS (Fleisher et al. 1999). Specifically, it was suggested that the extent of absorption of a poorly water-soluble, highly permeable BCS II drug is most likely increased, while it will remain unchanged for a highly water-soluble and permeable BCS I drug. In fact, the same trend was observed by Gu and coworkers, who evaluated the effect of food intake on the extent of absorption, defined as the area under the curve of the time–plasma concentration curve (AUC), by analyzing clinical data of 90 marketed drug products (Gu et al. 2007). For the majority of products containing a BCS I compound (67%), no statistically significant difference in the AUC in the fasted and fed state was observed. In contrast, more than 70% of the drug products comprising BCS II or BCS IV drugs

Fig. 1.1 Occurrence of food effects (positive, negative, or no effect) in percent by Biopharmaceutics Classifications System (BCS) category (Gu et al. 2007). Adapted with permission

exhibited a positive food effect as indicated by a significant increase in the AUC in the fed state compared to the fasted state (Fig. 1.1).

The positive food effect oftentimes encountered with poorly water-soluble drugs can be primarily ascribed to several physiological changes in the GI environment that ultimately increase drug solubility and dissolution. First of all, the intake of food is known to delay gastric emptying which, in turn, is beneficial in terms of absorption as it increases the time available for drug dissolution (Charman et al. 1997). Second, a substantial rise in the gastric and intestinal fluid volume in the fed state offers the potential for increased dissolution rates (Custodio et al. 2008). Furthermore, food intake stimulates the release of bile from the gallbladder into the duodenum where its components, primarily bile salts, cholesterol, and phospholipids, solubilize dietary lipids into mixed micelles (Hofmann and Mysels 1987). Similarly, these mixed micelles have the ability to incorporate lipophilic drug molecules potentially boosting drug solubility by several orders of magnitude (Dressman et al. 2007). Bile salts may also enhance the dissolution rate of poorly soluble drugs by improved wetting which is predominantly the case when their concentration stays below the critical micelle concentration. As an example, a study conducted in healthy male volunteers found that the oral bioavailability of danazol, a BCS II drug, was increased by 400% (Table 1.1.) when administered together with a lipid-rich meal (Sunesen et al. 2005). This was primarily attributed to the presence of bile salts and lecithin in the small intestine allowing for micellar solubilization of the drug. In addition, an

Table 1.1 Pharmacokinetic parameters and time to 50% gastric emptying ($T_{50\%}$) of danazol administered to healthy male volunteers orally in the fasted and fed state

| Treatment | C_{\max} (ng/mL) | T_{\max} (h) | AUC (h*ng/mL) | Bioavailability (%) | $T_{50\%}$ (min) |
|--------------|--------------------|------------------|------------------|---------------------|------------------|
| Fasted state | 25 (\pm 17) | 3.1 (\pm 0.7) | 120 (\pm 60) | 11 (\pm 5.2) | 13 (\pm 9) |
| Fed state | 60 (\pm 24) | 4.0 (\pm 1.1) | 469 (\pm 164) | 44 (\pm 12) | 49 (\pm 25) |

(mean \pm SD, $n=8$; Sunesen et al. 2005). Adapted with permission

increase in gastric emptying time from 13 min (fasted state) to 49 min (fed state) was considered to play a role in bioavailability enhancement.

In the case of weakly acidic or basic drugs, which in the aqueous GI environment exist in ionized and unionized form, variations in gastrointestinal pH due to food intake can significantly increase or decrease drug solubility. In healthy subjects, the gastric pH in the fasted state typically lies in the range of 1–3, but may temporarily rise to 4–7 after meal intake (Lee and Yang 2001; Dressman et al. 2007). Since the extent of ionization and consequently the solubility of a weakly acidic drug are greater at elevated pH, food intake may enhance drug dissolution in the stomach. In contrast, the extent of ionization of a weakly basic drug will be reduced at increased gastric pH, resulting in reduced dissolution and/or potential precipitation of already dissolved drug molecules.

Due to their high sensitivity to gastrointestinal changes caused by food intake, poorly soluble compounds are often associated with extremely variable and unpredictable oral bioavailability. Especially in the case of drugs that exhibit a narrow therapeutic window, sub-therapeutic, or toxic concentrations of the drug in the systemic circulation may easily occur. To prevent either scenario, patients generally have to adhere to certain food restrictions, potentially compromising patient compliance, and quality of life.

It should be noted though that the occurrence of food effects may be prevented by selection of an appropriate formulation design. Several formulation approaches that enhance drug solubility and therefore enable class II drugs to act as class I drugs have already been successfully applied to reduce or eliminate fed/fasted variability. These include, among others, nanoparticulate (Jinno et al. 2006; Sauron et al. 2006), self-emulsifying (Perlman et al. 2008; Woo et al. 2008), and solid dispersion-based drug-delivery systems (Klein et al. 2007), all of which will be addressed in depth in upcoming chapters.

The extent of oral bioavailability is affected not only by drug characteristics such as solubility and gastrointestinal permeability but also by a drug molecules susceptibility to intestinal and hepatic metabolism and active influx/efflux transporters.

The presence of metabolic enzymes of cytochrome P 450 (CYP 450) within the endoplasmic reticulum of hepatocytes and intestinal enterocytes may significantly decrease oral bioavailability of many drugs (Lee and Yang 2001; Paine et al. 2006). Smith et al. suggested that this will particularly be the case for drugs that are lipophilic and therefore easily cross cell membranes, thereby gaining access to CYP enzymes (Smith et al. 1996). Further analysis by Wu and Benet confirmed that highly permeable BCS I and BCS II drugs are primarily eliminated via metabolism, while poorly permeable BCS III and IV drugs are mostly eliminated unchanged into

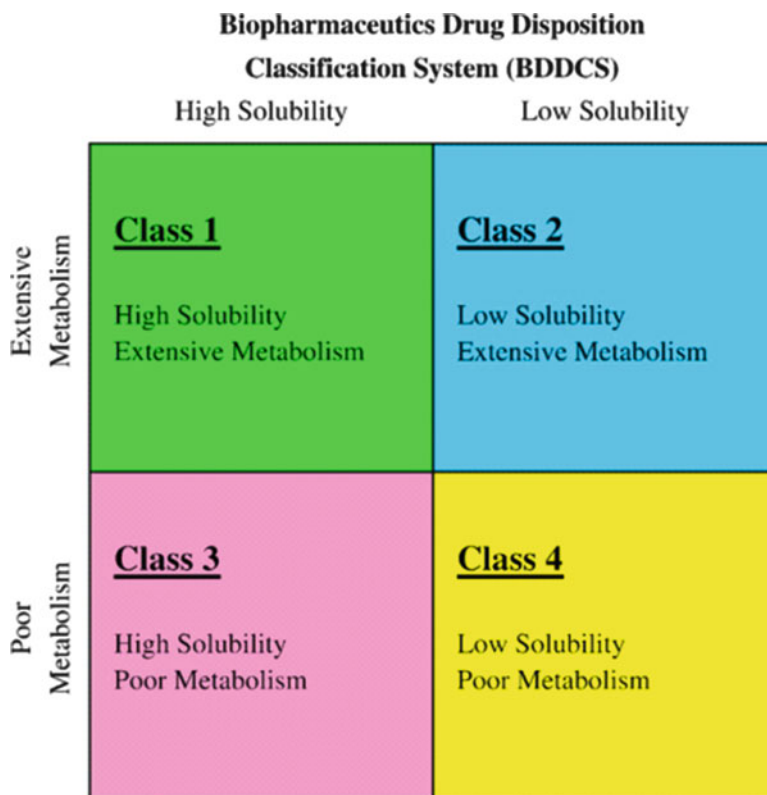

Fig. 1.2 The Biopharmaceutics Drug Disposition Classification System (BDDCS) (Custodio et al. 2008). Reprinted with permission

the urine and bile (Wu and Benet 2005). It should be, however, noted that the low/high permeability characteristics as defined in the BCS reflects the differences in access of the drug to metabolic enzymes within the cells and not necessarily differences in permeability into the cells (Custodio et al. 2008).

Based on their findings, Wu and Benet proposed the Biopharmaceutics Drug Disposition Classification System (BDDCS) in which drugs are categorized in terms of extent of metabolism and solubility as opposed to permeability and solubility used in the BCS (Fig. 1.2). According to the BDDCS, poorly soluble, highly permeable BCS II compounds are characterized by extensive metabolism defined as $\geq 70\%$ metabolism of an oral dose in vivo in humans.

The BDDCS also considers the influence of active uptake/efflux transporters on drug disposition as shown in Fig. 1.3. Since most BCS II compounds are substrates or inhibitors for P-glycoprotein (P-gp), a transmembrane efflux transporter, it is expected that the interplay of P-gp and metabolizing enzymes will notably influence the extent of metabolic extraction and oral bioavailability of BCS II substrates (Custodio et al. 2008).

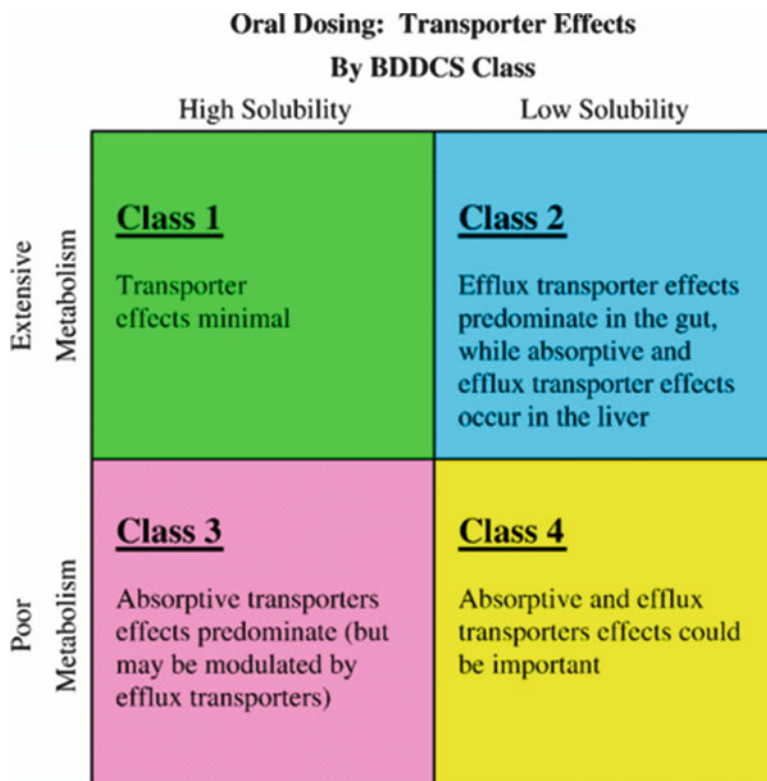

Fig. 1.3 Transporter effects, following oral dosing, by Biopharmaceutics Drug Disposition Classification System (BDDCS) class (Custodio et al. 2008). Reprinted with permission

Results from a number of studies aimed at understanding the interaction of CYP 450 enzymes and P-gp and its effect on compounds that are dual substrates suggest that both work synergistically to increase presystemic metabolism (Hochman et al. 2000). It is assumed that exposure of drugs, which are substrates of P-gp, to intestinal CYP 450 enzymes is increased due to repeated cycles of intracellular uptake and efflux. However, the complexity of metabolic enzyme-P-gp interactions is still only partially understood (Knight et al. 2006).

1.3 Parenteral Route of Administration

Parenteral administration is commonly defined as the injection of dosage forms by subcutaneous, intramuscular, intra-arterial, and intravenous (i.v.) routes (Jain 2008). In the case of i.v. administration, the drug is directly delivered to the bloodstream, thereby allowing for rapid distribution to highly perfused organs. The consequently

rapid onset of pharmacological effect that is achieved by i.v. administration is critical for several clinical conditions that require immediate action such as cardiac arrest and anaphylactic shock (Shi et al. 2009). In addition, i.v. administration is advantageous for drugs for which oral delivery would result in low and erratic bioavailability due to gastrointestinal degradation or significant presystemic/first-pass metabolism. Overall, i.v. administration offers excellent control over the actual dose and rate at which the drug is delivered, providing more predictable pharmacokinetic, and pharmacodynamic profiles than obtained after oral administration (Bhalla 2007).

Since i.v. formulations are directly injected into the bloodstream, they are subject to strict regulatory requirements regarding their physical and chemical stability as well as their microbiological characteristics. The latter implicates that products intended for i.v. administration must be sterile and free of pyrogens (Akers and Troy 2005). Besides, pH and tonicity of i.v. products should be close to physiological values in order to prevent irritation, pain, and hemolysis of blood cells. To achieve the highest possible in vivo tolerability for an i.v. product, it should ideally be formulated as an aqueous-based solution that is isotonic and possesses a pH of 7.4. Clearly, this is not feasible for drugs that are characterized by poor aqueous solubility at this specific pH. Generally, poorly soluble compounds may be solubilized by pH adjustment (if drug molecule is ionizable), the use of organic solvent mixtures, or mixed aqueous/organic cosolvents, and cyclodextrin complexation (Strickley 2004; Bracq et al. 2008). However, all these solubilization approaches are associated with major drawbacks such as increased toxicity or the possibility of drug precipitation upon injection and subsequent dilution (Yalkowsky et al. 1998).

Alternatively, the drug can be formulated in the form of solid particles which are suspended in aqueous media. The size distribution of intravenous suspensions is critical for safety and distribution of particles in vivo and generally restricted to the submicron range (Wong et al. 2008). Preventing particle agglomeration, aggregation, or crystal growth by adding suitable stabilizers is vital as an increase in particle size could result in the mechanical blockage of small-caliber arterioles and capillaries. The choice of stabilizers and generally excipients accepted for i.v. administration is, however, rather limited which presents a common challenge for all formulation strategies mentioned.

1.3.1 Challenges in Parenteral Delivery of Poorly Water-Soluble Drugs

Poorly soluble weak acids or bases may be solubilized by pH modification of the solution to be administered. Yet, if the drug is characterized by very low solubility, pH-adjustment to extreme values might be necessary to achieve the desired drug concentration in solution (Lee et al. 2003). It is recommended, however, that the pH for i.v. infusions should be in the range of 2–10 in order to reduce side effects such as irritation and pain at the injection side (Egger-Heigold 2005).

Side effects may occur not only due to extreme pH values but also due to potential precipitation of the drug upon injection. A change in pH caused by dilution in the bloodstream may reduce the solubility of the drug below the solubility limit resulting in precipitation. Buffer species as well as buffer strength have been identified as key factors influencing drug solubility and consequently precipitation in pH-adjusted formulations (Narazaki et al. 2007). It is essential to prevent precipitation as precipitated drug crystals may cause inflammation of the vein wall, also known as phlebitis, mainly due to mechanical irritation and prolonged drug exposure at the vein wall (Johnson et al. 2003). Besides, precipitation of solubilized drug molecules may result in erratic or reduced bioavailability as well as altered pharmacokinetics (Yalkowsky et al. 1998). For instance, precipitated particles in the low micron to submicron range may be taken up by macrophages of the reticuloendothelial system resulting in a significantly increased drug plasma clearance (Bittner and Mountfield 2002). Furthermore, dissolution of precipitated drug at later time points may increase the terminal half-life as well as the volume of distribution.

Drugs that are not sufficiently solubilized by pH adjustment or drugs that have no ionizable groups may be formulated using organic water-miscible cosolvents and surfactants. Frequently used cosolvents for i.v. formulations are propylene glycol, ethanol, and polyethylene glycols while commonly used surfactants include polysorbate 80, Cremophor EL, and Cremophor RH 60 (Strickley 2004; Bracq et al. 2008). Highly lipophilic compounds may even require formulation in a nonaqueous, organic vehicle comprising only water-miscible solvents and/or surfactants. These are commonly concentrates which are diluted with aqueous media prior to administration. Overall, the number and concentration of organic solvents and surfactants is limited as they may cause severe side effects. Organic solvents as well as surfactants are known to provoke hemolysis, the rupturing of erythrocytes (Reed and Yalkowsky 1987; Shalel et al. 2002). Resulting hemoglobin release into the blood plasma may induce vascular irritation, phlebitis, anemia, kernicterus, and acute renal failure (Krzyzaniak et al. 1997; Amin and Dannenfelser 2006). The hemolytic potential of these additives has been evaluated in numerous studies (Zaslavsky et al. 1978; Ohnishi and Sagitani 1993; Mottu et al. 2001). Yet, oftentimes conflicting results have been reported due to different methodologies used. Table 1.2 summarizes in vitro hemolysis data for different cosolvent systems obtained in rabbit, dog, and human blood compared to human in vivo data acquired from the literature (Amin and Dannenfelser 2006). For all vehicles a higher percentage of hemolysis is seen for data obtained with human blood followed by rabbit and dog blood; yet, the rank order of different vehicles evaluated is similar for the different species evaluated.

Just like solubilization via pH adjustment, solubilization by means of cosolvents has the limitation of potential drug precipitation (Li and Zhao 2007). Figure 1.4 exemplarily depicts the solubility curve of a drug at different cosolvent levels (squares) compared to the drug concentration curve based on dilution (dots). The saturation solubility of the drug in a 50% (v/v) cosolvent system is 2.4 mg/mL, while the drug is formulated at a concentration of 1.6 mg/mL. Upon injection, the concentrations of the cosolvent and drug will decrease linearly due to dilution in the bloodstream. In contrast, drug solubility will decrease exponentially, causing it to

Table 1.2 Detection of hemolysis by in vivo and in vitro methods

| Formulation composition | In vivo literature | In vitro (% hemolysis detected) | | |
|------------------------------------|--------------------|---------------------------------|--------------|-----------|
| | | Human blood | Rabbit blood | Dog blood |
| Normal saline (NS) | No | 0.0 | 0.0 | 0.0 |
| 10% EtOH in NS | No | 0.0 | 0.0 | 10.0 |
| 30% EtOH in NS | No | 0.0 | 0.0 | 2.5 |
| 40% PG in NS | Yes | 61.0 | 37.3 | 29.7 |
| 60% PG in water | Yes | 100.00 | 96.7 | 53.4 |
| 10% PG + 30% EtOH in NS | No | 0.0 | 0.0 | 0.0 |
| 10% EtOH + 20% PG in water | No | 8.8 | 0.0 | 0.3 |

Fig. 1.4 Illustration of precipitation of a drug formulated in a 50% (v/v) cosolvent system (Li and Zhao 2007). Reprinted with permission

fall below the actual drug concentration rapidly. This means that the drug is present in the supersaturated state where it is susceptible to precipitation. It has been suggested that the addition of surfactants to cosolvent formulations, even in small concentrations (0.05–0.5% w/v), may prevent precipitation upon i.v. administration (Li and Zhao 2007).

The formulation of i.v. products with surfactants, especially in high concentrations, has been associated with acute hypersensitivity reactions characterized by dyspnea, flushing, rash, chest pain, tachycardia, and hypotension (ten Tije et al. 2003). Paclitaxel, a poorly water-soluble molecule with antineoplastic activity, was originally

formulated in form of a nonaqueous solution for i.v. infusion (Taxol[®]), in which the drug is solubilized in a mixture of Cremphor EL and ethanol (Singla et al. 2002). This formulation can cause significant hypersensitivity reactions, which are primarily attributed to Cremphor EL, necessitating premedication of patients with steroids and antihistamines. Complement activation due to binding of the hydroxyl-rich surface of Cremphor EL to naturally occurring anti-cholesterol antibodies has been proposed as a possible underlying mechanism for the occurrence of these hypersensitivity reactions (Szebeni et al. 1998). Docetaxel, a semi-synthetic analog of paclitaxel, is solubilized with the nonionic surfactant polysorbate 80 in its marketed formulation Taxotere[®] (Engels et al. 2007). This concentrate is further diluted with 13% ethanol in water for injection and saline or dextrose solution before i.v. administration. Like Taxol[®], Taxotere[®] often results in severe side effects specifically, severe hypersensitivity reactions mainly caused due to the presence of polysorbate 80 in the formulation.

The use of surfactants in i.v. formulations may not only cause hypersensitivity reactions but also alter drug pharmacokinetics by interfering with distribution processes, transporters, or metabolic enzymes (Egger-Heigold 2005). It has been reported that Cremphor EL modifies the pharmacokinetics of several drugs such as etoposide, doxorubicin, and paclitaxel (Ellis et al. 1996; Webster et al. 1996; Sparreboom et al. 1996). A study conducted in mice, which received Taxol[®] (paclitaxel solubilized in Cremphor EL and ethanol) by i.v. injection at three different dose levels, revealed a nonlinear pharmacokinetic behavior of paclitaxel (Sparreboom et al. 1996). In particular, a disproportional increase in c_{\max} and a decrease in the plasma clearance upon dosage escalation were observed. In contrast, i.v. administration of a Cremphor EL-free solution of paclitaxel in the organic solvent dimethylacetamide resulted in a c_{\max} that varied proportionally with dosage as well as a dose-independent clearance. The same nonlinear pharmacokinetic was also observed in an in vivo study involving patients with solid tumors who were treated with different dose levels of Taxol[®] (van Zuylen et al. 2001). It has been suggested that the Cremphor EL-related nonlinear paclitaxel pharmacokinetics is caused by entrapment of the drug into Cremphor EL micelles which function as the primary carrier in the systemic circulation leading to a disproportionate paclitaxel accumulation in the plasma (Sparreboom et al. 1999).

Finally, complexation of poorly water-soluble drugs with cyclodextrins has been explored as an alternative approach for i.v. delivery of these troublesome compounds. Cyclodextrins are cyclic oligosaccharides composed of six, seven, or eight (α -1, 4)-linked α -D-glucopyranose units corresponding to α -, β -, and γ -cyclodextrins, respectively (Brewster and Loftsson 2007). They are characterized by a hydrophilic outer surface and a lipophilic inner cavity, which is capable of accommodating suitable drug compounds. Cyclodextrins employed for parenteral delivery, that is, hydroxypropyl- β -cyclodextrin, and sulfobutylether- β -cyclodextrin, are derivatives of β -cyclodextrin with increased aqueous solubility and improved in vivo safety profiles (Stella and He 2008). Cyclodextrins oftentimes solubilize drug molecules as a linear function of their concentration. Consequently, dilution of the formulation in the blood stream upon i.v. administration will result in a linear reduction of both

drug and cyclodextrin concentration. Based on that, drug precipitation that is oftentimes seen with cosolvent or pH-adjusted systems is very unlikely to occur with cyclodextrin-based formulations. Nevertheless, there are several shortcomings associated with the use of cyclodextrins as means of solubility enhancers. Solubilization by cyclodextrins is not generally applicable to all drug molecules. In order to successfully form a stable cyclodextrin-drug inclusion complex, the drug molecule needs to have the appropriate size, shape, and polarity to fit into the central cyclodextrin cavity (Radi and Eissa 2010). Drug release from cyclodextrin inclusion complexes after i.v. injection is generally rapid and quantitative, with the main driving force being the dilution in the blood stream (Stella et al. 1999). Problems may however arise for strongly bound drugs with high complex-forming constants where the drug does not rapidly dissociate from the complex potentially altering pharmacokinetics.

1.4 Pulmonary Route of Administration

Pulmonary drug delivery may be aimed at treating numerous diseases either locally or systemically. Local therapy of conditions such as asthma or pulmonary infections is advantageous in that drug concentrations at the site of action are maximized while systemic exposure and associated adverse effects are minimized. The pulmonary route of administration also offers several benefits for systemic delivery of drugs including a large absorptive surface area, a thin epithelial barrier, and low metabolic activity (Patton et al. 2004).

The respiratory system comprises the upper airways, including nasopharynx, trachea, and large bronchi, and the respiratory region, including the small bronchioles, and alveoli (Groneberg et al. 2003). It is known that the *trans*-epithelial transport of inhaled compounds will differ significantly among these regions. Transport in the upper airways is generally restricted by its lower surface area and blood flow as well as rapid clearance through the mucociliary escalator. Accordingly, drugs intended for systemic delivery need to be targeted to the respiratory region where high surface area and rich vascularization offer superior conditions for drug absorption.

Several factors in regards to the formulation, such as particle diameter, shape, density, or electrical charge, have been shown to influence where and to what extent aerosolized particles deposit in the lungs (Crowder et al. 2002; Saini et al. 2007). Particularly, it has been demonstrated that particles with mass median aerodynamic diameters (MMAD) of 1–3 μm preferentially deposit in the deep lungs (Heyder et al. 1986). Particles with MMAD larger than 5 μm primarily deposit in the upper airways and near-bronchial branching points where they are rapidly cleared while particles smaller than 1 μm are, to the most part, not deposited in the airways but rather exhaled after inspiration.

Formulations for pulmonary delivery are restricted not only to the appropriate particle size range but also to the use of specific and very few excipients. Generally, excipients intended for use in pulmonary products need to be either physiologically

compatible with lung tissue in terms of pH, tonicity, and immunogenic potential, or of endogenous nature in order to avoid airway hyper-responsiveness, spasticity, or inflammation (Tolman and Williams 2009; Pilcer and Amighi 2010).

Several formulations of poorly soluble drugs for pulmonary delivery have been developed and, in part, marketed. Formulation approaches employed mainly include solubilization in nonaqueous solvents and particle size reduction into the submicron range. Formulation development is however greatly challenged due to the very limited number of acceptable excipients and the fact that these can only be used in small concentrations in order to maintain adequate aerosol performance and prevent adverse physiological effects (Mogalian and Myrdal 2007).

1.4.1 Challenges in Pulmonary Delivery of Poorly Water-Soluble Drugs

In order to generate and deliver an aerosol of appropriate size distribution and reproducible dose to the lungs, different devices such as metered dose inhalers (MDIs), nebulizers, and dry powder inhalers (DPIs) have to be employed (Labiris and Dolovich 2003). Depending on the delivery device and the properties of the active pharmaceutical ingredient, inhalation products will be formulated with different types of excipients, i.e., to ensure effective aerosolization performance, to improve physical, or chemical stability of the API, or in the case of poorly soluble drugs to enhance solubility/dissolution.

MDIs emit an aerosol driven by a single propellant or a blend of various propellants upon activation of an appropriate valve system. Generally, propellants are subject to strict selection criteria with the key requirements being: benign toxicology, suitable boiling point, solvent capacity, and density, as well as nonflammability (Noakes 2002). Since chlorofluorocarbons (CFCs) exhibit all of these desirable propellant characteristics, they have long been the propellants of choice. However, due to their harmful effects on the ozone layer, it is required that pharmaceutical aerosols have to be reformulated with non-ozone-depleting propellants such as hydrofluoroalkanes (HFAs). In MDI formulations, the drug is either dissolved or suspended in the propellant(s). In the case of solution-based formulations, it is imperative that the drug has sufficient solubility to allow therapeutic doses to be delivered in a few actuations (Smyth 2003). The use of cosolvents such as ethanol often times enables solubilization of satisfactory amounts of lipophilic drugs in the propellant or propellant mixture of interest. As an example, beclomethasone dipropionate, a slightly water-soluble corticosteroid used in the treatment of asthma, is dissolved in the propellant HFA 134a with the help of ethanol in one of its marketed products (QVAR®). This cosolvent-based approach might however not be applicable for all drugs. Especially, in the case of drugs that are very poorly soluble or require a large delivered dose, great amounts of ethanol might be needed. This may be problematic in terms of aerosol performance as it has been demonstrated that increased ethanol concentrations can considerably affect aerosol characteristics. A study evaluating

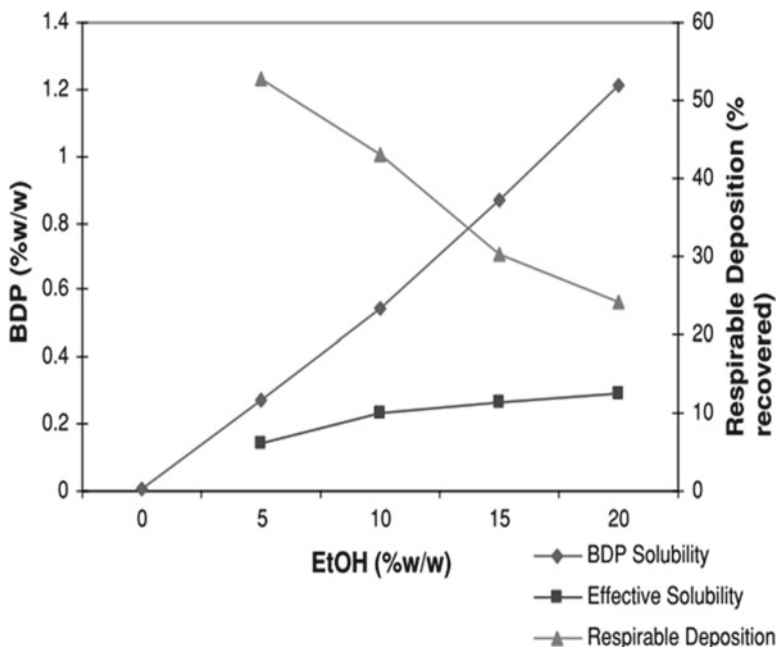

Fig. 1.5 “Effective solubility” (product of the drug solubility multiplied by the respirable deposition at a given ethanol level) as a function of ethanol concentration (% w/w). Also shown in the graph are the beclomethasone dipropionate solubility (% w/w) and respirable deposition as a function of ethanol concentration (% w/w) (Gupta et al. 2003). Reprinted with permission

solubility and product performance of beclomethasone dipropionate in various blends of HFA 134a and ethanol showed that with increasing ethanol concentrations, the solubility of the drug in the propellant was almost linearly increased. However, product performance was greatly reduced at ethanol concentrations above 10% (w/w) as illustrated by a decrease in the respirable deposition (Fig. 1.5; Gupta et al. 2003).

Besides its negative impact on MDI aerosolization performance, ethanol may also cause irritation of the lung tissue. Pulmonary tolerance testing of ethanol conducted in a rat model via intratracheal administration over 4 days only found limited cellular reactions, including minimal hypertrophy of goblet cells in the lungs and trachea, and minimal hyperplasia in the tracheal epithelial and slight lung inflammation (Montharu et al. 2010). Still, further studies are needed to accurately determine acute and chronic toxicity limits of inhaled ethanol in humans.

Alternatively to solution-based MDI formulations, suspension-based systems can be employed. Most poorly water-soluble corticosteroids intended for pulmonary delivery have a sufficiently low solubility in the traditionally used CFC propellants to be formulated in form of suspensions. To efficiently disperse drug particles of preferred sizes between 1 and 3 μm in the propellant system, surfactants are commonly employed. Specifically, surfactants will prevent particle agglomeration

which is vital as particle-size changes will lead to irregularities in the emitted dose. Challenges arise from the fact that the number of possible surfactants to choose from is rather limited, with currently only oleic acid, sorbitane trioleate (Span 85), and soya-derived lecithin being accepted for inhalation (Pilcer and Amighi 2010).

Nebulizers are used to aerosolize aqueous solutions or suspensions by means of compressed air (jet nebulizers) or a vibrating mesh (ultrasonic nebulizers). In the case of poorly water-soluble drugs, solutions may be obtained by employing different solubilizing agents such as nonaqueous solvents or cyclodextrins. Otherwise suspensions of micronized or even nanosized material which will show enhanced dissolution rates may be employed.

Solubilization and subsequent nebulization of poorly water-soluble drugs in the form of nonaqueous solutions have been attempted. This approach is however challenged by the generally lower tolerability of the lungs for nonaqueous solvents such as ethanol and propylene glycol. Cyclosporine A, a highly lyophilic immunosuppressant, was initially formulated in ethanol and the efficacy and pharmacokinetics of this formulation after nebulization evaluated in different animal models (Dowling et al. 1990; Blot et al. 1995; Mitruka et al. 1998). Even though inhaled solutions of cyclosporine resulted in high and sustained drug levels in the lung, local irritation due to the use of ethanol as a formulation vehicle was observed. As a result, further studies have been conducted using propylene glycol as the formulation vehicle. Only scant data are available regarding effects of propylene glycol on the respiratory tract after pulmonary administration. However, a recent 28-day repeat dose inhalation toxicity study in rats suggested its safety for inhalation therapy as no adverse respiratory or systemic effects of high doses of propylene glycol were seen (Wang et al. 2007). Still, the high viscosity of propylene glycol presents a significant challenge for effective aerosol generation via nebulization, generally requiring longer nebulization times and resulting in lower output rates (McCallion et al. 1995; Corcoran 2006).

As cyclodextrins have shown to be valuable excipients in the delivery of poorly soluble drugs via the oral or parenteral route, great interest has been created to extent their use into pulmonary delivery as well. Several studies have demonstrated that aqueous solutions containing inclusion complexes of poorly water-soluble drugs and cyclodextrins can be successfully nebulized with droplet sizes suitable for deep lung delivery (Tewes et al. 2008; Thi et al. 2009; Yang et al. 2010). Despite their potential benefits in pulmonary delivery of poorly soluble drugs, little data regarding their safety via this route of administration are available to date. A short-term toxicity study in mice assessing bronchoalveolar lavage, lung, and kidney histology as well as bronchial responsiveness after inhalation of 2-hydroxypropyl- β -cyclodextrin, randomly methylated- β -cyclodextrin, and γ -cyclodextrin concluded that the cyclodextrins tested were generally nontoxic at dosages between 20 and 100 mM (Evrard et al. 2004). Another study conducted in *in vitro* cell cultures demonstrated that the effect of cyclodextrins on respiratory cell metabolic activity and permeability was concentration-dependent and varied with cyclodextrin type (β or γ), chemical derivatization, and degree of substitution (Salem et al. 2009). Especially, methylated cyclodextrins, which have a high affinity for membrane lipids such as phosphatidylcholine and cholesterol, are able to permeate the airway epithelium.

Consequently, it cannot be excluded that cyclodextrins have the ability to be absorbed into the systemic circulation after pulmonary administration (Matilainen et al. 2008).

Alternatively to solutions, suspensions of poorly water-soluble drugs may be employed for inhalation therapy via nebulization. Considerable research has focused on the use of nanosuspensions which, due to their increased surface area, exhibit enhanced dissolution rates (Jacobs and Müller 2002; Tam et al. 2008; Yang et al. 2008). Nanoparticles are also more uniformly distributed throughout the carrier droplets generated by nebulization than microparticles, thereby promoting more efficient drug distribution throughout the alveoli (Jacobs and Müller 2002). Despite these advantageous characteristics of nanosuspensions, the formulation of stable nanoparticulate suspensions remains challenging as surfactants, required for efficient stabilization, are limited in number and concentration when used for inhalation products (see above).

Aqueous nanosuspensions may also be dried, i.e., employing spray-drying or lyophilization, to be used in DPIs. Delivery of drug nanoparticles by means of DPI is however problematic since the particles are too small for efficient lung deposition and are mostly exhaled after inspiration. “Trojan” micron-sized particles, which are porous structures completely composed of either nanoparticles or nanoparticles and suitable carrier materials such as sugars or phospholipids, have been suggested as an alternative (Tsapis et al. 2002). As a result of their larger size, they will more efficiently deposit in the deep lungs, where they then disassociate to release the nanoparticles. The *in vivo* performance of these types of particles has yet to be evaluated. Furthermore, inhalation of nanoparticles raises considerable concern regarding potential toxicity. Various studies that have evaluated the effects of inhaled ultrafine particles have reported inflammatory reactions as well as carcinogenicity (Oberdörster 1997; Renwick et al. 2004). It is assumed that nanoparticles high surface area leads to oxidative stress and calcium changes in alveolar macrophages and epithelial cells, thereby activating cells for inflammation (Renwick et al. 2001; Donaldson 2001). Inflammation as well as inflammatory cell-derived oxidants may, in turn, induce, and stimulate neoplastic transformation of epithelial cells (Driscoll 1997). Still most studies were conducted with insoluble, inorganic particles such as TiO_2 . It is likely that soluble or biodegradable excipients as principally employed for pulmonary drug delivery may behave quite differently.

1.5 Summary

The increasing percentage of NCEs characterized by poor aqueous solubility presents various challenges in the development of effective drug-delivery systems. Oral delivery of poorly soluble drugs is often characterized by low bioavailability as well as increased likelihood for food effects. With the advances in various solubilization and particle-size reduction technologies, the obstacles faced may however be addressed and enable successful delivery of a wide range of drugs via oral delivery.

One of the main challenges in the delivery of poorly soluble drugs via the pulmonary and parenteral route is the limited number of approved excipients. The development of novel excipients may offer new opportunities and enable more effective delivery of poorly soluble drugs. However, the time and costs involved in a complete toxicological evaluation of a novel excipient as well as the possibility of regulatory delays or even rejection may discourage pharmaceutical companies from developing new excipients.

Overall, significant achievements have already been made in the formulation of poorly soluble drugs. Several approaches aimed at enhancing solubility/dissolution such as nanosuspensions or cyclodextrin inclusion complexes have shown promising results in terms of enhanced *in vivo* performance. Still, concerns regarding the safety of certain excipients or delivery systems remain. Therefore, further studies need to be conducted in the future to make poorly soluble drugs available via various routes of delivery.

Method Capsule 1

Development of a Self-Emulsifying Formulation that Reduces the Food Effect for Torcetrapib

Based on the method reported by Perlman et al. (2008)

Objective

- To achieve a lower food effect and higher dose of torcetrapib per unit through the use of self-emulsifying formulation.

Equipment and Reagents

- Torcetrapib (Clog *P* 7.45; non-ionizable)
- Miglyol 812 BP (medium chain triglycerides)
- Triacetin (triacetyl glycerin)
- Polysorbate 80
- Capmul MCM (medium chain mono and diglycerides)
- Glass vessel
- Gelatin softgel shells
- Rotary-die encapsulation machine

Method

- Excipients are added to glass vessel (semisolid excipient Capmul MCM melted prior to addition).
- Mixture is stirred until it is homogeneous.
- Then the desired amount of the drug is added.
- The resulting mixture is stirred at ambient temperature with occasional scraping of the vessel walls until solution is obtained.
- Softgels are manufactured on a rotary-die machine by encapsulation using a shell prepared from gelatin, glycerin, and water.

Results

- The mean droplet size of the emulsion formed by mixing the formulation and water at a ratio of 1:100 by five times gentle inversion was determined to be 257 nm.
- Softgel capsules stored for 6 weeks at 5°C/75% RH, 30°C/60% RH, and 40°C/75% RH showed no change in potency as analyzed by HPLC. Also no sign of crystallization in the fill under any condition based on microscopic examination was found.
- The use of the lipophilic, GRAS cosolvent triacetin in the formulation allowed a twofold increase in the dose per capsule as compared to the formulation used in early clinical trials where the drug was dissolved in Mygliol 812 BP only.
- Pharmacokinetic studies in dogs demonstrated that the food effect seen with Mygliol softgels was reduced from five to threefold with the Mygliol/Triacetin/Polysorbate 80/Capmul MCM formulation.

Method Capsule 2**High Bioavailability from Nebulized Itraconazole Nanoparticle Dispersions with Biocompatible Stabilizers**

Based on the method reported by Yang et al. (2008)

Objective

- To develop an itraconazole nanoparticle dispersion for pulmonary delivery by nebulization that does not require the use of synthetic polymers and surfactants to achieve high supersaturation values in vitro and high bioavailability in vivo.

Equipment and Reagents

- Itraconazole (ITZ)
- Mannitol
- Lecithin
- 1,4-Dioxane
- Ultra-rapid freezing (URF) apparatus
- Lyophilizer

Method

- Lecithin (118 mg) is dissolved in a mixture of 1,4-dioxane and purified water (65/35, v/v) cosolvent system (200 mL) using a magnetic stirrer.
- ITZ (588 mg) and mannitol (294 mg) are subsequently dissolved in the mixture; this provides a dissolved solids ratio of ITZ:mannitol:lecithin of 1:0.5:0.2 by weight.

- The solution is rapidly frozen using the URF apparatus in which the solution is applied to a cryogenic solid substrate cooled to -70°C .
- The resultant frozen solids are collected and lyophilized.

Results

- Particle-size distributions of lyophilized ITZ powder redispersed in water showed a narrow size range with a D50 and D90 (diameter at which the cumulative sample volume is under 50 and 90%, respectively) of 230 and 540 nm, respectively.
- ITZ nanoparticles were found to be amorphous as indicated by the absence of the characteristic crystalline peaks of ITZ and mannitol.
- ITZ nanoparticles produced supersaturation levels 27 times the crystalline solubility upon dissolution in simulated lung fluid.
- The colloidal dispersion obtained after redispersion of the powder in water demonstrated optimal aerodynamic properties with a fine particle fraction of 66.96% and a mass median aerodynamic diameter of nebulized droplets of 2.38 μm .
- An in vivo single-dose 24 h pharmacokinetics study of the nebulized colloidal dispersion demonstrated substantial lung deposition and systemic absorption with blood levels reaching a peak of 1.6 $\mu\text{g}/\text{mL}$ serum in 2 h.

Method Capsule 3

Amorphous Cyclosporin Nanodispersions for Enhanced Pulmonary Deposition and Dissolution

Based on the method reported by Tam et al. (2008)

Objective

- To nebulize stable amorphous nanoparticle dispersions of Cyclosporine A to achieve high fine particle fractions and high levels of absorption into the lung epithelium.

Equipment and Reagents

- Cyclosporin A
- Polysorbate 80
- Liquid nitrogen
- Methanol
- Glass vessel
- Temperature-controlled water bath
- Rotary evaporator

Method

- 15 g of methanol containing 3.2% w/w cyclosporine A is injected into 50 g deionized water containing an appropriate amount of polysorbate 80 and maintained at 3°C by means of a temperature-controlled water bath.

- Methanol is then separated from the aqueous dispersion via vacuum distillation.
- If the dry powder is desired, the aqueous dispersion can be frozen drop-wise into liquid nitrogen and then be lyophilized.

Results

- Static light scattering results demonstrated a cyclosporine to polysorbate 80 ratio of 1:0.1 produced particles with an average diameter of 300 nm.
- The absence of characteristic crystalline cyclosporine A peaks in XRD patterns indicated a primarily amorphous character.
- Dissolution of the aqueous cyclosporine A dispersion produced supersaturation values 18 times the aqueous equilibrium solubility of the drug.
- The sizes of the aerosolized aqueous droplets (1–4 μm) obtained by nebulization were found to be optimal for deep lung deposition.
- Nebulization of the dispersion to mice produced therapeutic lung levels and systemic concentrations below toxic limits.

Method Capsule 4 Production and Characterization of a Budesonide Nanosuspension for Pulmonary Administration

Based on the method reported by Jacobs and Müller (2002)

Objective

- To develop a budesonide nanosuspension by high-pressure homogenization and to investigate the aerosolization properties of this nanosuspension

Equipment and Reagents

- Budesonide
- Soy lecithin
- Span 85
- Tyloxapol
- Cetylalcohol
- Ultra-Turrax
- High-pressure homogenizer

Method

- The surfactants are dissolved or dispersed in warm ($\sim 40^\circ\text{C}$) bidistilled water by using an Ultra-Turrax.
- Budesonide is then dispersed in the aqueous surfactant solution/dispersion by using the Ultra-Turrax for 1 min at 9,500 rpm.
- The obtained premix is homogenized by using a Micron LAB 40 homogenizer at two cycles at 150 bar and two cycles at 500 bar as a kind of premilling and then 20 homogenization cycles at 1,500 bar to obtain the final product.

Results

- A combination of lecithin (0.5%, w/w) and tyloxapol (0.2%, w/w) proved to be most suitable to stabilize budesonide (1%, w/w) nanosuspension.
- The mean particle size of this nanosuspension was 500 nm as analyzed by photon correlation spectroscopy.
- The scale-up of the formulation from 40 to 300 mL was successful with similar size distributions obtained for both batch sizes.
- The mean particle size as determined by photon correlation spectroscopy did not change after nebulization of the nanosuspension indicating suitability for pulmonary delivery.
- Nanosuspension stored at room temperature was stable in terms of size distribution over 1 year period.

Method Capsule 5**Trojan Particles: Large Porous Carriers of Nanoparticles for Drug Delivery**

Based on the method reported by Tsapis et al. (2002)

Objective

- To combine the drug release and delivery potential of nanoparticle (NP) systems with the ease of flow, processing, and aerosolization potential of large porous particle (LPP) systems by spray-drying solutions of NPs into large porous NP (LPNP) aggregates.

Equipment and Reagents

- 1,2-Dipalmitoyl-sn-glycero-3-phosphocholine (DPPC)
- 1,2-dimyristoyl-sn-glycero-3-phosphoethanolamine (DMPE)
- Lactose monohydrate
- Hydroxypropylcellulose
- Bovine serum albumin (BSA)
- Ethanol
- Aqueous suspensions of surfactant-free carboxylate-modified polystyrene NP (PS-NP) or aqueous suspensions (pH 9) of Nyacol 9,950 colloidal silica NP
- Spray-dryer

Method

- Solutions of NPs were prepared by mixing ethanol and water (70:30, v/v) to the desired w/v fraction.
- If desired, additional excipients may be included, e.g., sugars, lipids such as DPPC and DMPE, polymers, or proteins.

- The resulting mixture is spray-dried under the following conditions: the inlet temperature is fixed at 110°C, the outlet temperature is about 46°C, a V24 rotary atomizer spinning at 20,000 rpm is used, and the feed rate of the solution is 70 mL/min, the drying air flow rate is 98 kg/h.
- Spray-dried particles are collected with a 6 in. cyclone.

Results

- The chemical nature of the NPs seemed to be of little importance, since LPNPs were also successfully produced with colloidal silica NPs instead of PS-NPs.
- The formation of LPNPs appears to be generally independent of the size of the NPs (25 nm and 170 nm NP were tested), provided they are much smaller than the ultimate physical dimension of the spray-dried LPNP.
- In all cases, the LPNPs had a solid deformable shell, consisting of several layers of NPs, and a wrinkled structure indicative of a low relative density, making their aerodynamic properties highly favorable.
- Additional control over LPNPs physical characteristics is achieved by adding other components to the spray-dried solutions, including sugars, lipids (DPPC, DMPE), polymers (hydroxypropylcellulose), and proteins (BSA).

Chapter 2

Optimizing the Formulation of Poorly Water-Soluble Drugs

Kevin P. O'Donnell and Robert O. Williams III

Abstract With as high as 60% of drugs in company pipelines exhibiting poor aqueous solubility, the ability to successfully develop a poorly water-soluble drug has become essential. Gaining a detailed understanding of a compound through preformulation studies can be especially challenging for poorly water-soluble drugs limiting their development. Therefore, this chapter focuses on the application of preformulation studies essential in understanding a poorly water-soluble drug, including solubility studies, solid-state characterization of the active ingredient and formulations thereof, and in vitro and in vivo testing of the lead formulations.

2.1 Introduction

It is estimated that 60% of drugs in company pipelines are poorly water soluble. Many of these active pharmaceutical ingredients (APIs) are designated BCS class II compounds (low solubility and high permeability), making their aqueous solubility the limiting factor regarding bioavailability (Fahr and Liu 2007). This has led to numerous novel formulation approaches such as particle engineering, alterations of the API into a salt form, amorphization of the compound, the use of surface-active agents or cosolvents, inclusion of polymeric stabilizers for supersaturation, and the generation of solid dispersions/solutions, as well as many other novel techniques. Each of these techniques focuses on improving the extent or rate at which the drug enters solution in an effort to increase the bioavailability. During this formulation process, it is important to perform the correct studies to ensure that the development is proceeding in the desired direction. This includes tests designed to gain an

understanding of the API alone, as well as experiments necessary in formulation optimization.

In the following sections, numerous analytical and experimental techniques will be presented, focusing on understanding and optimizing poorly water-soluble drugs or formulations thereof during development. This includes solubility testing, solid-state characterization studies, in vitro dissolution work, and in vivo dose administration.

2.1.1 Solubility Studies

As mentioned, approximately 60% of drugs in company pipelines are poorly water-soluble, being designated BCS class II compounds (low solubility and high permeability), making their aqueous solubility the limiting factor regarding bioavailability; formulation will thus focus on improving the extent or rate at which the drug enters solution (Fahr and Liu 2007). Additionally, an understanding of a compound's solubility is required for pharmacological, toxicological, and pharmacokinetic studies as a solution of the drug is often required to perform such studies (Mashru et al. 2005; Teijeiro and Briñón 2006). Aqueous solubility determination has proven extremely difficult for poorly water-soluble (PWS) drugs. This section describes both experimental and predictive (mathematical) methods for determining the aqueous solubility of a drug.

2.1.1.1 Solubility Prediction

The solubility of a solid compound may be mathematically predicted using the equation developed by Yalkowsky and Valvani (1980). Here, solubility (S_w) is defined in terms of the melting temperature (T_m), octanol–water partition coefficient (P_c), and the entropy of melting (ΔS_f) of the substance such that:

$$\log S_w = -1.00 \log P_c - \frac{1.11 \Delta S_f (T_m - 25)}{1364} + 0.54.$$

Analysis of multiple compounds led to a proposed universal value of 56.5 J/mol/K for the entropy of melting and a reduction of the equation to:

$$\log S_w = -1.05 \log P_c - 0.012 t_m + 0.87.$$

When applying the equation to a new chemical entity, the true entropy of melting should be experimentally determined (i.e., by differential scanning calorimetry) to be more precise.

More recently, (Jain and Yalkowsky 2001) analyzed 580 compounds and further refined the above equation such that:

$$\log S_w = -1.031 \log P_c - 0.0102 t_m + 0.679.$$

Fig. 2.1 Calculated solubility from the GSE versus experimentally determined solubility. $N=1,026$. Reproduced with permission from Elsevier

This equation is more commonly referred to as the general solubility equation (GSE) and can be used as an empirical estimation of the aqueous solubility of a compound.

Baena et al. have employed these equations in the solubility prediction of acetanilide derivatives. All three equations provided accurate predictions of the aqueous solubility of acetanilide and phenacetin; however, they were not accurate at estimating the aqueous solubility of acetaminophen (Baena et al. 2004). A similar study by Venkatesh et al. determined the solubility of cosalane by multiple methods. Indeed, empirical estimation yielded a difference of three orders of magnitude compared to experimental determination for the PWS drug (Venkatesh et al. 1996).

Ran et al. analyzed 1,026 nonelectrolytes by the GSE and compared them to their respective experimentally determined aqueous solubilities. As can be seen in Fig. 2.1, empirical calculation correlates well with experimental determination for many of the compounds analyzed (Radha et al. 2010). However, these studies demonstrate that while empirical analysis may provide a good estimation of solubility and should be employed when limited quantities of drug are available, they are not accurate for all compounds and experimental testing must be performed to validate the calculated results.

2.1.2 *Experimental Aqueous Solubility Determination*

The most widely employed experimental method for solubility determination is by direct determination in aqueous suspension. In this method, excess drug is placed in a designated volume of water and held at constant temperature. Samples are taken periodically and the drug concentration is determined analytically (i.e., HPLC analysis).

For example, Seedher et al. analyzed the solubility of seven PWS antidiabetic drugs. In their study, excess drug was placed in 5-mL of water in a sealed container. The suspensions were held at 25°C and placed under magnetic stirring for 24 h at which point equilibrium was obtained. The suspensions were then centrifuged, filtered through a 0.45- μ m membrane, and analyzed by UV absorbance for drug quantification (Seedher and Kanojia 2009). Applying the same method, the researchers also screened numerous cosolvents for their ability to enhance solubilization. It should be noted that the centrifugation and filtration steps are critical as they eliminate potential seeds for recrystallization and ensure that no particulate matter is dissolved upon dilution for analysis, which may provide inaccurate results.

Teijeiro analyzed the solubility of AZT-Iso, a derivative of zidovudine, by direct determination in aqueous suspension using excess drug in 4 mL of water under constant shaking. Again, filtration was applied following equilibration and the samples were analyzed by UV absorbance (Teijeiro and Briñón 2006).

It is crucial that compounds analyzed by direct determination in aqueous suspension be allowed to reach equilibrium. The aforementioned studies required only 24 h to achieve equilibration; however, for many PWS drugs this time is insufficient. Venkatesh found that cosalane required 48 h to reach equilibrium at 25°C. In contrast, Shaw et al. found that 5 days were required to attain equilibrium for ibuprofen at 37°C (Shaw et al. 2005). For a new chemical entity, it is recommended that samples be taken every 8 h up to 24 h, and then every 24 h after for 4 days. If the determined concentration has not reached a plateau, the study may be continued for longer durations of time if necessary.

2.1.3 *pH-Solubility Profiles*

The pH-solubility profile of a PWS drug can be a driving factor in its course of development. Compounds such as itraconazole show a marked reduction in solubility upon entry into neutral media creating the need for gastric absorption or supersaturation in the intestine to enhance bioavailability.

The direct determination in aqueous suspension method can be adapted to provide pH-solubility profiles. For example, Wang et al. placed excess sildenafil citrate in 10 mL of deionized water in multiple 15-mL vials. The pH values of individual vials were then titrated to a pH of 3–11. These suspensions were then placed at 37°C for 48 h. Following confirmation that no shift in pH had occurred, samples

Table 2.1 pH-solubility profile of sildenafil. Reproduced with permission from Elsevier

| | pH | | | | | | | | |
|--------------------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 |
| Solubility (mg/ml) | 6.965 | 7.077 | 2.068 | 0.114 | 0.025 | 0.027 | 0.040 | 0.103 | 0.322 |
| S.D. | 0.092 | 0.047 | 0.042 | 0.001 | 0.001 | 0.001 | 0.001 | 0.001 | 0.058 |

were filtered through 0.2- μm filters, diluted with mobile phase, and analyzed by HPLC (Wang et al. 2008). Table 2.1 shows that, indeed, the solubility of sildenafil drastically decreases above pH 4. Norfloxacin was analyzed in the same manner; however, in this case a solution of NaCl was added to each vial in amounts necessary to achieve constant ionic strength among samples (Ahumada et al. 1993). The direct determination in aqueous suspension method was also employed for the pH-solubility profile of haloperidol free base and the corresponding hydrochloride and mesylate salts to identify the more soluble species (Li et al. 2005). In this iteration, a single vial of each compound was prepared by adding excess solids to 5 mL of water. The suspensions were then titrated with HCl or NaOH solutions to the desired pH and allowed to equilibrate at 37°C for 24 h. At 24 h, the pH was confirmed and an aliquot taken for analysis. The pH was then adjusted to the next desired level, the vials resealed, and the equilibration and sampling processes repeated. Indeed, such a process allows identification of the more soluble salt in media at physiologically relevant pH values.

A modified version of the method has been used to determine the solubility of a synthetic recombinant plague antigen (D'Souza et al. 2009). The researchers first prepared buffers with pH values ranging from 3 to 10. Aliquots of a stock solution of the monomer were then diluted with one of the buffers to a concentration of 360 $\mu\text{g/mL}$. This solution was then placed in a dialysis cassette and dialyzed against the respective diluting buffer for 15 h under refrigeration. The dialysate was then filtered and analyzed by UV absorbance for solubilized compound.

The direct determination in aqueous suspension method is not without limitations. Substances with extremely low solubilities may fall outside of the detection limits for many available analytical techniques. Additionally, molecules with stability issues may undergo complexation or aggregation, yielding inaccurate results. An alternative to the direct determination in aqueous suspension method was presented by Avdeef et al., in which the solubility is determined through acid–base titration. Using experimentally determined $\text{p}K_a$ and $\log P$ values, the solubility of 12 generic drugs was determined and compared to values obtained by direct determination in aqueous suspension. Indeed, the data correlated well. Uniquely, the method not only allows for intrinsic solubility determination but also provides a complete pH-solubility profile for the drugs analyzed (Avdeef et al. 2000). This method was applied using the pSOL instrument and corresponding software in determining the solubility profile of an experimental PWS compound NP-647 (Khomane et al. 2011). The dissolution titration method provided the researchers with both intrinsic solubility and pH-solubility data.

Fig. 2.2 Rotating disk intrinsic dissolution apparatus diagram. From Viegas et al. (2001a, b)

2.1.4 Intrinsic Dissolution

The intrinsic dissolution rate of an API is the rate of dissolution of the compound under constant conditions (i.e., identical surface area, temperature, agitation rate, pH, and ionic strength of the dissolution media for all samples) and is used to demonstrate equivalency of raw components (i.e., comparison of salt vs. free base) and physical mixtures of drugs and excipients or final formulations (Viegas et al. 2001a, b; Lee et al. 2011). USP 32/NF 27 identifies two apparatuses for the determination of intrinsic dissolution rates: rotating disk and stationary disk. Regardless of the unit selected for dissolution analysis, the surface area of the material to be tested is held constant by generating a compact within the body of the device. This is done by attaching the body to a baseplate, filling the body cavity with a known amount of powder, placing a punch on top of the powder surface, and compressing the powder by means of a hydraulic press to a given pressure for a predetermined period of time. Figures 2.2 and 2.3 depict a rotating disk and stationary disk assembly, respectively.

2.1.4.1 Compact Preparation

The preparation of an adequate compact for analysis is crucial in intrinsic dissolution testing to ensure that a constant surface area is maintained throughout the test. The term adequate compact refers to a compact which will not disintegrate during prolonged exposure to the dissolution media and that has been compressed sufficiently to remove all air from the powder bed, thereby preventing the formation of capillaries and potential surface bubbles. The USP states that compression for 1 min

Fig. 2.3 Stationary disk intrinsic dissolution apparatus. Reproduced with permission from Dissolution Technologies

at 15 MPa is sufficient; however, this is not universal and the compression pressure and time must be tailored to the formulation at hand such that upon testing the compact does not disintegrate. High compression forces and excessive times may induce physical changes in a powder such as polymorphism or crystallization, and a compact formed by the selected parameters should be analyzed for such transitions. For example, a novel quinolinone derivative required compression at 196 MPa to yield a solid nondisintegrating compact. X-ray diffraction revealed that no transformations took place upon compression, thereby validating the compaction procedure and obtained dissolution results (Kimura et al. 2001). In a study of 13 different APIs, a compression time of 1 min was sufficient for all materials; however, the compression force required varied from 1.96 to 19.6 MPa (Zakeri-Milani et al. 2009). Viegas et al. (2001a, b) applied a force of 2,000 psi for 4–5 min to achieve a satisfactory disk. As can be seen, the compression force will vary greatly between formulations; however, a study by Yu and co-workers demonstrated that the compression force applied during compact formation does not influence the intrinsic dissolution rate of a material, provided the compact does not undergo physical alterations (i.e., polymorphic transitions or crystallization) or disintegrate during testing (Yu et al., 2004).

2.1.4.2 Intrinsic Dissolution Testing

The above mentioned study by Yu additionally demonstrated that dissolution volume (provided sink conditions are maintained) and disk distance from the vessel bottom do not influence the intrinsic dissolution rate of a given compound. However, Viegas showed that for both types of ID apparatuses the rotation speed or paddle speed greatly influenced the dissolution rate and therefore must be held constant when comparing formulations. The literature supports values between 50 and 150 rpm, with slower speeds being used for compacts more prone to disintegration. During dissolution testing, the media is to be heated to physiological temperature of 37°C. The standard apparatus 2 volume of 900 mL is often used; however, smaller volumes such as 250 mL can also be employed when larger volumes will lead to concentrations below the limit of detection for the compound (Viegas et al. 2001a, b; Lee et al. 2011).

The media for dissolution testing must be adequately degassed prior to experimentation. This not only prevents potential oxidative degradation of dissolved compound but also prevents potential bubble formation on the surface of the compact during testing, thereby disrupting the factor of constant surface area. Multiple methods can be employed to degas the media, including sparging with an inert gas (i.e., helium or nitrogen) for 30 min at 6 psi, stirring heated media under vacuum (41°C, 160 mmHg), sonication (30 min), sonication under vacuum (60 mmHg), and equilibration at 37°C for 24 h (Diebold and Dressman 1998; Gao et al. 2006). Selection of the appropriate method for the study at hand is at the discretion of the researcher.

Sampling time points will depend upon the compound under analysis. Sampling at 5 min intervals for 1 h has proven sufficient to obtain a dissolution profile with a region of linearity. Although no solid mass should be present as the compact is non-disintegrating, filtration of the withdrawn media through a 0.45-micron filter is recommended. As per the USP/NF 32/27, the amount versus time profile is plotted; however, only the *initial* linear region is used for intrinsic dissolution rate calculation. Regions of nonlinearity are excluded from data analysis. The constant surface area dissolution rate (i.e., slope) is then reported in the units of mass/s and the dissolution flux reported as mass /cm²/s. Flux is obtained by dividing the calculated dissolution rate by the surface area of the compact and is the parameter to be reported with regard to intrinsic dissolution data reporting.

2.2 Solid-State Characterization

Solid-state characterization of APIs, excipients, and combinations thereof is invaluable during product development. The techniques outlined in the following sections are utilized to gain an understanding of the API's physical nature, interactions with excipients, and response to processing and environmental conditions. The following sections do not contain detailed information regarding the theory behind each technique. Rather, a discussion of how the methods should be utilized during PWS drug formulation is provided.

2.2.1 Thermal Analysis

2.2.1.1 Differential Scanning Calorimetry

Differential scanning calorimetry (DSC) is widely used for physical characterization of drugs and formulations thereof including identification of melting, crystallization, and thermal transition phenomena, as well as the associated changes in entropy and enthalpy. DSC has the advantage of requiring only minimal amounts of the compounds under study and a rapid timeline to completion. During analysis, a sample and reference pan are subjected to a heating profile and the energy and temperatures associated with thermal events are assessed. For a detailed understanding of DSC theory, the reader is referred to (Craig and Reading 2007; Schick 2009). The following sections discuss the application of DSC to preformulation studies, including selection of appropriate parameters, identification of prominent thermal events, and application in polymorph and excipient screening.

Parameter Selection Method

As mentioned earlier, DSC has the advantage of requiring only minimal amounts of the compounds under study and a rapid timeline to completion. Reported sample sizes range from 2 to 15 mg and can be selected to optimize the response profile. Increasing the sample size will increase the sensitivity of the system; however, this will also decrease the resolution of the trace. The converse holds true with smaller samples increasing the resolution at the sacrifice of sensitivity. It should additionally be noted that peak maximum temperature for thermal events will increase with increasing sample size and thus the sample size must be held nominal throughout a study.

While multiple pans can be used for sample analysis (i.e., aluminum crimp top and aluminum hermetic), it is imperative that during preparation sample contact with the pan be maximized. Improper sample contact can increase thermal lag within the system, creating inconsistent results. The most prevalent pan type for analysis is aluminum crimp top pans such as those offered by Perkin-Elmer. For materials which may undergo transitions induced by the pressure applied during crimping, a noncrimped pan with lid can be used, or pans capable of being hermetically sealed can be employed. Whichever pan type is selected, it is absolutely essential that the corresponding reference pan be identical to that used for sampling (lid included if utilized), except only the material being analyzed. Additionally, it is crucial that samples which may undergo volume expansion upon heating be limited in their sample size to prevent spillage from the pan to the DSC cell surface. Such events can also be prevented by selection of the correct pan type. If contamination of the cell surface occurs, the system must be cleaned following manufacturer guidelines and recalibrated prior to subsequent analyses.

The heating rate selected for testing must be a compromise between resolution, sensitivity, and time. While slower heating rates allow greater separation of thermal

events (i.e., increased resolution), the sensitivity to these events is reduced and the run time for each analysis is greatly increased. Conversely, higher heating rates will decrease the resolution, as thermal events separated by only a few degrees will overlap. However, faster heating rates generate greater sensitivity to thermal transitions, allowing visualization of minor events while also drastically reducing the time for analysis. In fact, a ramp rate of ≥ 100 K/min was required in order to detect weak transitions occurring in a lyophilized protein sample and corresponding formulations thereof (Carpenter et al. 2009). Additionally, increases in ramp rates will alter the T_{\max} of the melting endotherm (Abbas et al., 2008). Ramp rates for analysis of pharmaceutical materials of 2, 5, or 10 K/min are most prevalent in the literature. Regardless of the rate selected, all samples in a given study must be analyzed under the same heating rate for the purpose of comparison.

It is necessary to calibrate the instrument using standards of known temperatures and enthalpies of melting under the identical conditions to be used during analysis. The reference material(s) should have melting temperatures near those of the analytical samples to ensure accuracy. Materials for calibration include zinc, indium, aluminum, lead, silver, tin, gallium, and gold (Cammenga et al. 1993). Additional calibration standards include naphthalene, benzyl, benzoic acid, and anisic acid, which have proven useful for calibrating temperatures between the melting temperatures of the metals indium and gallium (Charsley et al. 2006).

Modulated differential scanning calorimetry (mDSC) provides a linear heating ramp with a superimposed temperature oscillation yielding a modulation in the heating profile. mDSC provides identical data as that obtained by traditional DSC analysis (i.e., total heat flow). However, Fourier transform separation of the DSC signal allows the heat-capacity-related component (reversible signal) to be isolated. Furthermore, subtraction of the reversing component from the total heat flow allows for isolation of the nonreversing component of the scan (Aldén et al. 1995; Sauer et al. 2000). This ultimately allows the researcher to better visualize thermal events, as no exothermal events are present in the reversing signal. When mDSC is to be used, the underlying heating rate should be selected as outlined above based on the required resolution-to-sensitivity relationship. However, additional parameters are required, including the modulation temperature and frequency thereof. Selection of these parameters will be based on the applied heating rate as it is desired to have six modulations over the temperature range of a thermal event. As such, slower heating rates are often employed (i.e., 2–5 K/min) to ensure that these criteria are met. Modulation amplitudes should range between 0.1 and 2 K, as larger amplitudes may adversely affect data (Schawe 1996).

Thermal Events

Proper identification of the thermal events occurring upon heating of a sample can prove rather challenging in practice. The most prevalent thermal event identified by DSC analysis is that of melting. Upon reaching the melt temperature of a substance, the sample will remain isothermal until the entire sample has melted, as a

length of time is required to overcome the thermal lag across the sample. During this time, the trace yields an endothermic event; however, the manner in which the melting temperature (T_m) is reported based on this event varies among researchers. T_m has been reported at the initial deviation from baseline, at the temperature of onset of the endothermic peak, the temperature at the peak, or the temperature at which the thermogram returns to baseline. While these values may vary by as little as 3°C for highly pure substances displaying narrow melting peaks, substances with low purity or compositions containing multiple crystalline forms (i.e., semi-crystalline polymers) yield broad melting endotherms, causing large differences in T_m based on the report method (Brown 2001; Craig and Reading 2007). As peak broadening may occur in the presence of various excipients, or the pure substance itself may have a broad melting endotherm, the initial deviation, onset, and return to baseline temperatures may vary drastically among samples in a single study. However, the peak temperature is likely to remain relatively unchanged in the absence of formulation component interactions provided the sample size and heating rate are held constant, making its selection as the reporting temperature more reliable (Abbas et al. 2008).

Amorphous systems such as solid solutions are becoming highly prevalent in the development of PWS drugs. Of great importance to these polymeric and amorphous systems is the glass transition temperature (T_g). The nature of the glass transition temperature has been discussed in numerous ways, including relaxation processes and changes of free volume in a system; however, at its simplest, the glass transition temperature is a change in the heat capacity of the material and is observed as an endothermic step change in the baseline of the DSC trace. Analysis of the reversing heat flow obtained through mDSC provides the best visualization of the T_g event. The T_g of a material will vary slightly based on the selected heating rate and frequency for mDSC, with increased frequencies increasing the T_g , and, therefore, should be held constant for all samples in a given study to ensure accuracy in their comparison (Schawe 1996). As will be discussed in a subsequent section, polymer miscibility is crucial for amorphous systems to ensure homogeneity and stability and, oftentimes, the T_g values of a system are indicative of miscibility. The theoretical glass transition temperature of a system can be predicted using the Gordon–Taylor equation:

$$T_{g12} = \frac{w_1 T_{g1} + K w_2 T_{g2}}{w_1 + K w_2},$$

where T_{g1} and T_{g2} are the glass transition temperatures of raw components 1 and 2, respectively, and w is the weight fraction of the corresponding components. The value of K , the ratio of the components free volume, is such that:

$$K = \frac{\rho_1 \Delta\alpha_1}{\rho_2 \Delta\alpha_2},$$

Fig. 2.4 Reversing heatflow DSC profile of Itraconazole and HP-55 solid dispersions prepared by Ultra Rapid Freezing. Reproduced with permission from Elsevier

with values for $\Delta\alpha$ being found in the literature. For materials in which $\Delta\alpha$ is not available, the value of K can be estimated using the true densities of components 1 and 2 such that:

$$K \cong \frac{\rho_1 T_{g1}}{\rho_2 T_{g2}}$$

Direct comparison of the theoretical (calculated) T_g to the experimentally observed T_g allows assessment of drug–polymer or polymer–polymer miscibility (Gordon and Taylor 1952; Boyer and Simha 1973).

As the thermal event associated with the glass transition occurs over a broad temperature range (i.e., 10°C), the T_g has been reported in multiple ways, including step onset, midpoint, and endpoint temperatures. Analogous to T_m , the exact onset and endpoint temperatures may not be easily discernable on the trace. Therefore, calculation of the midpoint via the software associated with the unit at hand is the recommended means of interpreting T_g . Figure 2.4 depicts the reversing heat flow of formulations of itraconazole and hydroxypropylmethyl cellulose phthalate NF (HP55). Here, the glass transition temperature can readily be observed as a shift in baseline. As the ratio of drug to polymer changes, the T_g shifts and indeed this shift correlated well with the theoretical T_g predicted by the above-mentioned Gordon–Taylor equation. It should be noted that at high drug loadings, the melting endotherm of itraconazole can be observed. This is attributed to recrystallization occurring upon heating without sufficient polymeric stabilization (Overhoff et al. 2007).

Recrystallization is an exothermic event and, as such, it is not observed on the reversing heat flow profile. Examination of the corresponding heat flow in the above example reveals itraconazole to recrystallize between 110 and 130°C, depending on the polymer concentration of the system. Recrystallization occurs as a result of increased molecular mobility and subsequent molecular rearrangement during heating and can be observed in poorly stabilized amorphous systems following the glass transition event but prior to the melting endotherm. This can also be observed following polymorphic transitions (to be discussed), in which following melting of form I the material recrystallizes into form II with subsequent melting of form II, if sufficient time is provided for recrystallization (i.e., slow heating rates) (Alves et al. 2010). As decomposition events may also appear as exothermic peaks, differentiation between the two must be confirmed. This can be accomplished by supplemental thermogravimetric analysis (TGA) which will be discussed in the coming sections.

Polymorphic Transformations

The presence of an undesired polymorphic form of an API within a formulation may drastically alter the performance of the product, as the different polymorphs of a given API possess different physical properties. An understanding of these polymorphic forms with regard to their prevalence and transformations will assist the formulation scientist in optimizing the formulation. As physical properties are different for each polymorph of a given API, the T_m values of each polymorph can readily be used for their identification with exothermic events indicating species conversion (Bergese et al. 2003). For example, DSC analysis of polymorph II of rifampicin exhibits an endothermic peak at 193.9°C due to melting. A subsequent exothermic recrystallization is observed at 209.4°C as polymorph II recrystallizes into form I (Alves et al. 2010). When attempting to identify the polymorphs present in a system, it is imperative that the appropriate heating rate be selected for analysis to ensure that the energy applied by the system does not induce a transformation leading to improper identification within a formulation. The PWS drug nateglinide polymorphs B and H have T_m 's of 128 and 138°C, respectively. In order to properly identify the two forms when analyzed together, a heating rate of 10 K/min was employed. Indeed, at rates faster than 10 K/min the peaks overlapped hindering identification, while slower heating rates allowed sufficient time for transformation of form B to H (Bruni et al. 2011). It was additionally shown in this example that the grinding process (mortar/pestle) for preparation of the mixtures of the polymorphs induced the B-to-H transformation.

Transformations may occur as a result of processing conditions during production. As will be discussed in the next section, an understanding of API stability in the presence of the excipients to be used for the formulation is vital to ensure product performance. This includes assessment of process-induced polymorphic transformations. For example, form II of an experimental compound (drug Z) displays desirable dissolution characteristics over form I. Development of the product for tableting led to the inclusion of stearic acid in the formulation to prevent sticking.

However, it was found that the addition of stearic acid to the formulation with subsequent drying of the wet granulated mass at elevated temperatures induced a transformation to form I, thereby drastically reducing dissolution rates. This was confirmed via DSC analysis of granulated mass compared to thermograms of physical mixtures. Indeed, the physical mixture of form II in the presence of stearic acid displayed melting endotherms for both polymorphic forms, indicating partial conversion to the undesirable form (Wang et al. 2010).

Drug–Excipient Interactions

It should be immediately noted that many of the API–excipient interactions observed in DSC analysis, as well as the polymorphic transformations previously discussed, occur at temperatures drastically higher than those to be experienced in real-world application, with the exception of thermal processing techniques such as hot-melt extrusion. This must be considered when analyzing results to ensure that constituents are not incorrectly deemed incompatible.

Determination of the stability of an API in the presence of excipients requires analysis of the raw components, a physical blend of the components, and a processed sample of the components. The physical mixture should be prepared in a manner that does not introduce heat, moisture, or force into the system. Gentle blending of the powders in the desired ratio in a mortar with a spatula at ambient temperatures is recommended. The processed sample may be as simple as a co-ground mixture (i.e., grinding via mortar pestle for a minimum of 15 min) or may be a final formulation such as a tablet or hot-melt extrudate that has been ground for analysis. Analysis of the raw individual components will allow identification of thermal events associated with the isolated material such as the melting, recrystallization, and glass transition (if applicable) temperatures outlined above. Subsequent analysis of physical blends and processed material can then be inspected for shifts, disappearances or appearances of thermal events, or variations in the enthalpy values thereof (Mura et al. 1998a). In order to promote interactions, concentrations of excipients are often employed which far exceed the amount to be present in the final formulation. For example, a 1:1 physical mixture of carbamazepine-to-stearic acid (typically present in tablets at the 0.5–2% level) demonstrates a polymorphic transition that is unlikely to occur in a final formulation containing minimal amounts of the excipient (Joshi et al. 2002). In contrast, the transition described above for drug Z occurred using the actual amount of stearic acid to be employed during the granulation process, indicating a strong incompatibility. A 1:1 physical blend of picotamide with various excipients demonstrated that ascorbic and tartaric acids resulted in degradation of the drug upon heating. The same effect was also observed for processed samples; however, as mentioned above, the temperatures at which this interaction took place were drastically higher than those a final formulation would experience necessitating confirmation. Indeed, analysis of freshly prepared samples and stored samples at room temperature by X-ray diffraction (XRD) revealed that no interaction occurred and the DSC data were falsely identifying an incompatibility (Mura et al. 1998a, b).

The indication of drug–excipient interactions may not be detrimental to the formulation, but rather a desired interaction such as polymeric miscibility. DSC has been widely used in determining drug–polymer interactions, with emphasis on drug miscibility in the polymer during formulation of solid dispersions. Indeed, identification of the polymer in which the drug is most miscible will aid in the formulation of a single-phase system (Mora et al. 2006). Prior to the analysis of formulations, physical blends of the drug and polymer are analyzed by DSC to isolate polymers displaying the highest miscibility with the API. A negative shift in the melting endotherm (i.e., melting point depression) indicates miscibility at the ratio tested. A complete disappearance of the melting endotherm indicates the absence of crystalline API and solubilization of the API within polymeric carrier (Konno et al. 2008). Such an event also demonstrates amorphization of the API or inclusion complexation within a material such as cyclodextrins (Cappello et al. 2007). Polymers identified as being most highly miscible should be analyzed by TGA for verification that the absent melting endotherm is not due to degradation of the API (Hughey et al. 2010).

Upon formation of a solid dispersion, the drug and polymer are intimately mixed such that the system, as described above, will have a single intermediate T_g . Miscible systems, therefore, should only display this intermediate value and the appearance of multiple T_g 's is indicative of incomplete mixing, or drug or polymer-rich domains. Although the presence of a single experimental T_g intermediate to that of the polymer and API alone is a strong indicator of a homogeneous system, it is necessary to perform supplemental studies to ensure that such a product has truly been obtained. For example, Raman mapping of solid dispersions has demonstrated that a system displaying a single T_g in fact contained drug-rich domains, ultimately leading to recrystallization-related stability issues upon storage (Qian et al. 2010). The PWS drug irbesartan has been prepared into solid dispersions with tartaric acid, mannitol, PVP, and HPMC in an effort to increase aqueous solubility. mDSC analysis of the raw component (4–6 mg sample) revealed a melting endotherm at approximately 185°C. Preparation of a quench-cooled sample allowed for analysis of amorphous irbesartan in the absence of any excipients which showed a single T_g at 71.7°C with no subsequent recrystallization event. DSC analysis revealed a single T_g for irbesartan–tartaric acid dispersions indicating good miscibility. However, irbesartan–mannitol formulations presented two T_g values corresponding to the T_g 's of mannitol and irbesartan, suggesting an immiscible system. Similar results were obtained for both PVP and HPMC, indicating the drug is not miscible in the selected carriers and that reformulation is necessary in order to achieve a true solid solution (Chawla and Bansal 2008).

2.2.1.2 Thermogravimetric Analysis

A secondary thermal analytical technique which can stand alone or be complementary to DSC is TGA. Similar to DSC a small quantity of sample (sample sizes range identically to DSC) is placed in a metal crucible and exposed to a heating profile under an

inert atmosphere during analysis. However, as the name implies, TGA provides the researcher with variations in sample mass as a function of temperature, rather than the deviations in heat capacity. Examples of these reactions include the evolution of bound solvents, such as dehydration, or thermal decomposition of the product.

Parameter selection (i.e., temperature range and heating rate) depends upon the intention of the data. If TGA is to be used complementary to DSC, the identical temperature range and heating rate employed in for DSC must be selected for TGA. This will allow for superimposition of the thermal profiles and a direct comparison of thermal events. If superimposition of the data is not performed, a unique heating profile may be assigned regardless of that used for DSC. This includes isothermal analysis at elevated temperature in the study of reaction rates.

Thermal Decomposition

TGA has been broadly used in the study of thermal decomposition; however, it must be noted that such studies are only appropriate for materials which exhibit a weight loss upon decomposition. A study of numerous pharmaceutical excipients provided information of their thermal stability. While many of the excipients demonstrated a single-step weight loss upon reaching their respective thermal instability point, it is possible to observe multiple mechanisms concurrently. Lactose monohydrate exhibits multiple-step weight loss under TGA. The first step, observed between 106°C and 164°C, can be attributed to the dehydration of the bound water molecule. The second step from 216 to 339°C is attributed to thermal decomposition (Filho et al., 2009). The thermal stability of drugs can also be assessed as was demonstrated by obidoxime chloride. Indeed, the decomposition occurred over a wide range of temperatures, beginning at 118°C and continuing to 328°C. TGA revealed that the drug underwent a 10% weight loss at 208°C (Radha et al., 2010). TGA profiles overlaid with DSC profiles of rifampicin demonstrated that the exothermic events evidenced in DSC analysis were indeed decomposition events (Alves et al. 2010).

Excipient Interactions

Similar to DSC, TGA allows one to study the thermal compatibility of an API with multiple excipients. Such information is invaluable for formulations intended for thermal production processes such as hot-melt extrusion (HME). Indeed, drug-excipient compatibility at elevated temperatures may be drastically reduced compared to ambient conditions. TGA analysis of hydrocortisone in the presence of the polymers HPMC E3 and PVPVA 64 demonstrated that while all materials experienced decomposition at approximately 200°C, the presence of the polymer did not induce degradation of the API at lower temperatures (DiNunzio et al. 2008). Contrarily, TGA analysis of an experimental compound (ROA) in the presence of Eudragit® L100-55 demonstrated a significantly higher weight loss than predicted based on the data obtained from the individual components indicating API-excipient incompatibility (Fig. 2.5). Similar results were observed in the ROA-HPMCAS blends (Hughey et al. 2010). In the above-mentioned example of

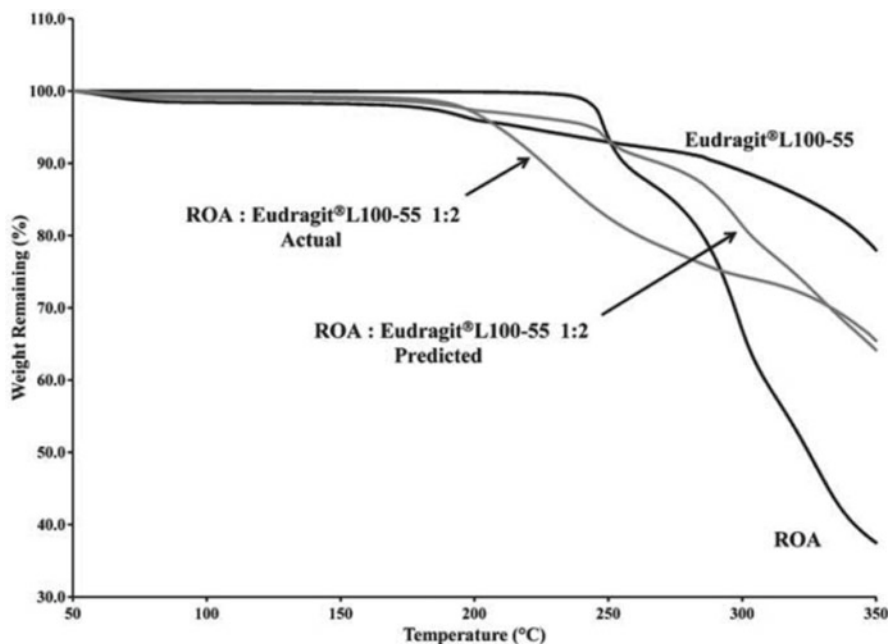

Fig. 2.5 API thermal decomposition in the presence of Eudragit L100-55

obidoxime chloride, the drug in the presence of multiple tableting excipients was also assessed by TGA. Indeed, it was shown that none of the tested excipients altered the decomposition profile of the API.

2.2.2 Fourier Transform Infrared Spectroscopy

Fourier transform infrared spectroscopy (FTIR) allows one to gain information regarding the molecular confirmation of a material based on characteristic molecular vibrations that absorb in the infrared region. There are multiple variations of FTIR analysis, including diffuse reflectance (DRIFT) and attenuated total reflectance (ATR). Each has its own advantages and selection of the appropriate unit will be at the discretion of the researcher; however, the focus of the sections below will be on ATR–FTIR as it requires minimal alteration of the sample prior to analysis.

2.2.2.1 Sample Preparation

Sample preparation will be dependent upon the type of FTIR analysis to be performed. For traditional FTIR analysis, the material to be analyzed is blended with a diluent such as potassium bromide (KBr) and compressed into a transparent pellet. This requires manual grinding of the sample prior to blending or concurrently with

the KBr, making preparation of hard or elastic materials problematic. Drug concentration within the pellet should be low, approximately 1% w/w. Once compressed, the samples should be analyzed immediately and it is recommended that a co-ground powder not be allowed to stand for long periods of time prior to pelletization for the purposes of stability. Products containing caffeine were analyzed by blending the pharmaceutical powder at a concentration of 1% w/w with KBr. Samples of this blend were then immediately compressed into a thin pellet for analysis while portions were stored for later analysis. Uniquely, the caffeine/KBr pellet proved to be stable once prepared for greater than 3 months, displaying an identical concentration of caffeine on day 90 as on the day of preparation with no alterations to the absorption spectrum. In contrast, storage of the prepared, uncompressed caffeine/KBr powder revealed instability with pellets prepared 30 days post blending, yielding drastically reduced caffeine concentrations (Baucells et al. 1993). The preparation of biologic samples in this manner is not recommended. In fact, KBr compression has proven to lead to protein unfolding as well as protein aggregation and loss of enzymatic activity (Chan et al. 1996; Wolkers and Oldenhof 2005). Similar to traditional FTIR, diffuse reflectance IR (DRIFT) requires the use of a diluent in sample preparation. KBr or a similar species such as KCl has been used during analysis. However, unlike traditional FTIR, the sample does not require mechanical compaction into a pellet. DRIFT does require that the blend be of uniform particle size for accuracy, creating difficulties for materials that are difficult to triturate and materials that may be chemically altered by the grinding process. Additionally, samples such as the caffeine discussed above require immediate analysis to ensure stability of the physical blend (Hartauer et al., 1992; Sitar Curin et al. 1997).

Attenuated total reflectance FTIR (ATR-FTIR) employs a crystal surface upon which the material to be analyzed is placed. For information regarding ATR-FTIR theory, the reader is referred to Buffeteau et al. (Buffeteau et al. 1996). ATR-FTIR has the unique advantage of minimal to no sample preparation prior to analysis. Powder blends or ground formulations (i.e., ground extrudates) do not require the addition of supplemental materials such as KBr. Additionally, it is possible to place an unground sample directly on the crystal for analysis, a method useful in assessing homogeneity at the surface of a product. The sample to be analyzed is placed directly on the internal reflection element (IRE), a high-refractive-index crystal such as diamond, and pressure is applied top down using a pressure applicator fit to the ATR-FTIR in use. The crucial element in ATR-FTIR sample preparation is ensuring an even and reproducible contact between the sample and internal reflection element. It has been shown that improper contact will yield inconsistencies in absorption band intensities. This includes insufficient contact (i.e., too little pressure) as well as too strong contact with the latter, capable of damaging both the sample and the crystal used as the IRE (Buffeteau et al. 1996; Salari and Young 1998). The pressure devices supplied by manufacturers are graduated nominally, such as a scale of 1–5 as that on the Foundation Series ATR attachments from Thermo Fisher Scientific. Selection of the correct application pressure must therefore be determined on a case-to-case basis. It should be noted that collection of the background spectrum must be performed without the pressure applicator engaged for powder samples.

2.2.2.2 Polymorph Screening

As mentioned above, ATR–FTIR requires no sample preparation prior to analysis save minor compression to ensure contact with the IRE. As such, the potential for process-induced polymorphism during sample preparation is limited, making the technique advantageous in polymorph screening. Analysis of the fingerprint region of the IR spectrum allows for identification of characteristic absorption bands which are unique to each polymorphic form. When a given polymorph is analyzed alone, spectral differences are readily apparent due to broadening of bands or the appearance and disappearance of absorption bands. Additionally, it has been shown that the summated absorption spectra of blends of polymorphs allow for identification of the species present. In fact, a study of the three ganciclovir polymorphs demonstrated that mathematical addition of the pure polymorphic spectra matched that of experimental blends of the polymorphs, thus allowing their accurate identification in formulations (Salari and Young 1998).

2.2.2.3 Excipient Interactions

Appearance of new absorption bands, broadening of bands, or alterations in intensity are the primary events associated with excipient interaction (Abbas et al. 2008). For an experimental compound BG 637, superimposition of the IR spectra of the drug obtained by DRIFT analysis over API–excipient blends yielded no alterations in the spectra, indicating no interactions with the tableting excipients tested. This result was confirmed via DSC and X-ray diffraction.

ATR–FTIR analysis of omeprazole sodium isomers and isomer–mannitol blends was performed not only on raw powders but also on compacts thereof. While the spectra of the powder mixtures did not display any differences, disk samples (1 cm diameter, 2 mm thickness) prepared via compression at 7 tons for 5 min proved unique, indicating interaction with the mannitol. Samples of the *R*-isomer compact displayed two distinct peaks corresponding to amino and imino group stretching (3,425 and 3,318 cm^{-1} , respectively), while the *S*-isomer compact solely displayed stretching corresponding to the amino group (Agatonovic-Kustrin et al. 2008). Such a method allows analysis of powder blends used for tableting as well as the final formulation in solid form.

2.2.3 X-Ray Diffraction

XRD is the measurement of the intensity of X-rays scattered by electrons bound to atoms and the corresponding phase shifts that occur as a result of the position of the atom. For a detailed explanation of XRD theory, the reader is referred to Dinnebier and Billinge (2008). XRD is typically a nondestructive test (i.e., the analyzed material can be recovered) and, as will be discussed, is highly useful for determining

differences in crystal structure (i.e., polymorphs), drug–excipient interactions, and identifying amorphous systems.

Prior to analysis, it is necessary to calibrate and optimize the device to be used for testing. This can be done by use of various reference standards such as those offered by the National Institute of Standards and Technology (NIST). Standard Reference Material 674b consists of four oxide powders to be used as internal standards or calibrators for an XRD unit: ZnO, TiO₂, Cr₂O₃, and CeO₂. Alternatively, standards of materials with well-understood diffraction patterns can be used such as alumina, mica, or silicon pellets.

2.2.3.1 Parameter Selection

During sample analysis, the operator will be required to input a number of parameters for each scan, including the scan range in degrees on a 2Θ scale, the step size (degrees per step), and the count time for each step (often referred to as dwell time). Assigning the proper parameters is crucial to ensure that adequate peak shape is obtained while minimizing processing time. For the first scan of a new API, it is necessary to analyze a very broad range, such as $5\text{--}120^\circ$ on the 2Θ scale. This will allow for identification of the characteristic crystalline peaks and subsequent analyses should be shortened to include only the footprint region.

Twenty data points per peak are desired to ensure adequate peak shape. In order to obtain this value, the researcher must alter the step size of each scan. For highly crystalline materials, a step size of 0.02° is adequate to meet this requirement. For materials exhibiting broad peaks, this value can be increased to shorten the run time while still maintaining the 20 data points per peak. In order to optimize the step size, the powder should be analyzed over a very narrow range, such as $2\text{--}5^\circ$ 2Θ , in a region containing a characteristic crystalline peak(s) over a range of step sizes. Cameron and Armstrong analyzed quartz from 67 to 69° 2Θ and varied the step size from 0.1 to 0.01° 2Θ in order to find the optimum step. Identification of the step size in which the diffractogram decays to baseline following the peak was selected as optimum (Cameron and Armstrong 1988). If upon return to baseline the inception of a new peak is immediate, a shorter step size should be selected to increase resolution.

Oftentimes, the step size and dwell time are considered together as a scan rate. For example, analysis of tenofovir disoproxil fumarate (TDF) was reported as being conducted from 4 to 40° at a rate of $4^\circ/\text{min}$ (Lee et al. 2010). Prevalent rates in the literature are between 0.5 and $4^\circ/\text{min}$.

The final parameter that must be determined is the dwell time. While a longer dwell time will increase the signal-to-noise ratio and improve counting statistics, it will also drastically increase the duration of a run. This is especially true for methods utilizing small step sizes. Therefore, in order to ensure timely analysis, the shortest dwell time, which provides a strong signal of all characteristic peaks without significant interference from the baseline, should be selected. This parameter will be most influential for systems lacking strong crystallinity, such

Fig. 2.6 XRD patterns of three polymorphic forms of TDF. Forms B and I are similar while Form A is unique. Reproduced with permission from American Chemical Society

as pharmaceutical systems containing a polymer, in which case longer dwell times will aid peak structure. Dwell times of 1–5 s can be employed, with times of 1–3 s being most prevalent in practice.

2.2.3.2 Polymorph Screening

As mentioned earlier, XRD analysis reveals phase shifts that occur as a result of atomic position within a material. Therefore, alterations in crystal structure that arise as a physical result of polymorphism can often be detected by XRD. This can be observed as a shift in a major characteristic peak, or the appearance or disappearance of peaks in the diffraction pattern. XRD analysis of the three polymorphs of TDF reveals that the diffraction patterns for forms B and I are similar, making their definite distinction difficult. However, form A contains multiple peaks not present in the diffraction patterns of the other polymorphs as well as the absence of one characteristic peak near 30°, making its identification absolute (Fig. 2.6). Kirk et al. demonstrated that three of four generated lactose polymorphs crystallize with monoclinic unit cells by XRD employing a range of 5–40° and a step size of 0.014767° and a 2 second dwell time (Kirk and Blatchford 2007). In another work, a variable

Table 2.2 Optimization of scan parameters for XRD analysis. Reproduced with permission from Elsevier

| Combination | Step time (s) | Step size (°) | Scan rate (° 2 θ /min) | Recording time (min) | No. of identifiable peaks |
|-------------|---------------|---------------|-------------------------------|----------------------|---------------------------|
| A | 0.5 | 0.025 | 3 | 12.33 | 1 |
| B | 0.5 | 0.0125 | 1.5 | 24.67 | 1 |
| C | 1 | 0.0125 | 0.75 | 49.33 | 2 |
| D | 5 | 0.05 | 0.6 | 61.66 | 4 |
| E | 5 | 0.0125 | 0.15 | 246.66 | 4 |

temperature cell was utilized and the XRD pattern of mebendazole was analyzed as a function of temperature to assess polymorphic transformations that occur due to temperature variation (de Villiers et al. 2005). Indeed, it was seen that at temperatures above 180°C a transformation to the more thermodynamically stable polymorph occurred.

Olanzapine can crystallize into 25 different crystalline structures of which seven are active pharmaceutically. Identification and quantification of each polymorph are necessary throughout the development cycle of a formulation containing such a compound to ensure that the final product is of acceptable quality. Tiwari et al. examined two polymorphs of the compound by XRD. Prior to analysis, the unit was calibrated with a silicon pellet. The scan was then optimized by varying the dwell time and step size such that the maximum number of identifiable peaks were obtained. As can be seen in Table 2.2, a dwell time of 5 s with a step size of 0.05° produced the greatest number of identifiable peaks in the shortest amount of time. In order to accurately quantify the amount of a given polymorph present in a mixture, each form must be analyzed as a pure sample. The highest-intensity peak is then selected and the intensity of the pure polymorph is set to 100%. The ratio of intensities for the selected peak in the mixture compared to the pure polymorph provides the percent present in the mixture. This, however, cannot be employed in the case of olanzapine, as the highest-intensity peaks overlap for multiple forms (Tiwari et al. 2007). However, screening of mannitol demonstrated that even with similar polymorphic forms coupling sample rotation with particle-size reduction increases the ability to differentiate the forms present. In the case of mannitol, it allowed identification of the individual components down to approximately the 1% level (Campbell Roberts et al., 2002).

2.2.3.3 Excipient Interactions

Changes in the XRD pattern may occur as a result of drug–excipient interactions. Such alterations include the conversion to a unique polymorphic form, or amorphous to crystalline transitions. For example, a sample of pure β -form carbamazepine displays a characteristic peak at 13°, while the α -form displays this peak as well as an additional peak at 8.8° 2 θ . In a study of physical mixtures of pure β -form

Fig. 2.7 XRD patterns of experimental compound BMS-488043 bulk material, physical blend with PVP and solid dispersions thereof. Reproduced with permission from John Wiley and Sons

carbamazepine in combination with various tableting excipients, it was seen that the characteristic peak at 13° was present in all samples. However, following storage at 55°C for 3 weeks, a combination of carbamazepine and stearic acid displayed the additional peak at 8.8° , indicating a conversion to the α -form. This was attributed to partial solubilization of carbamazepine in steric acid at elevated temperatures followed by recrystallization upon cooling (Joshi et al. 2002). Indeed, stability studies, to be discussed later, often rely on alterations in XRD patterns as an indication of formulation stability.

An amorphous material will yield an XRD pattern termed a “halo” which is a gradual rise and fall of the baseline with no distinct peaks. As many processing techniques focus on rendering the drug amorphous, XRD can be utilized to identify whether or not a drug or formulation is amorphous. This can be complicated when polymeric systems are used, as most polymers used in pharmaceutical applications are amorphous in nature. At low drug loadings, the amorphous signal from the polymer may overshadow or mask the crystalline pattern of the drug. As such, physical mixtures identical in drug:polymer ratio to that used in processing must be analyzed to ensure that the pattern is validated. Tobyn et al. analyzed an experimental compound as a solid dispersion with PVP at various drug-to-polymer ratios. As can be seen in Fig. 2.7, the bulk drug product is highly crystalline with many characteristic peaks (parameters: $2\text{--}60^\circ$ 2Θ , $2^\circ/\text{min}$ scan rate, calibration with mica and alumina reference standards). At a 50:50 ratio of drug-to-PVP the formulation produced an amorphous halo, indicating amorphization of the drug. This was confirmed using a

Fig. 2.8 Surface area enlargement as a result of particle-size reduction. From Junghanns and Mueller (2008)

dry blend of the materials at the same ratio. While a decrease in peak intensity can be observed for the 50:50 physical mixture, the peaks are still present, indicating that processing indeed rendered the drug amorphous. Additionally, it can be seen that at higher drug loading levels the process did not generate or stabilize the drug in the amorphous form (Tobyn et al. 2009).

2.2.4 Specific Surface Area

Many formulation approaches have been applied to overcome aqueous solubility issues including, but not limited to, the addition of solubilizing agents (i.e., cremophor EL), complexing agents (i.e. cyclodextrins), or the generation of a salt form of the API. As an alternative to formulating the API in one of these novel ways, many researchers are focusing on particle engineering techniques which decrease particle size or generate a porous system as a means of increasing aqueous solubility.

Substantial particle-size reduction, or the formation of a porous system, will yield a significant increase in surface area for the powder (Fig. 2.8). The Noyes–Whitney equation describes the dissolution velocity as:

$$\frac{dW}{dt} = \frac{DA(C_s - C)}{L}$$

here, dW/dt is the dissolution rate, A is the surface area, C is the API concentration in the bulk dissolution media, C_s is the concentration of API in the diffusion layer around the solid, D is the diffusion coefficient, and L is the diffusion layer thickness. It can be observed that an increase in the surface area value, A , will increase the dissolution velocity (Junghanns and Mueller 2008; Lenhardt et al. 2008). Furthermore, a substantial decrease in particle size will cause an increase in dissolution pressure resulting in higher saturation solubilities (Mosharraf et al. 1999).

Measurement of the surface area may therefore offer insight into the relative dissolution rate of an engineered or processed powder, serving as a screening process between batches or production methods.

2.2.4.1 BET Surface Area Analysis

Surface area (SA) analysis of pharmaceutical powders is often assessed via gas adsorption methods. In these methods, a nonreactive gas is adsorbed to the surface of the material at or near the boiling point of the liquid adsorptive at a single or multiple pressures. The quantity of gas molecules required to form a monolayer of adsorbed gas on the powder surface is determined and using the average diameter of a single molecule the SA is determined (Condon 2006). This is done via mathematical modeling of the adsorption isotherms (amount adsorbed vs. adsorptive pressure), with the most established model being BET analysis. For a detailed summary of the theory behind BET isotherm analysis, the reader is referred to Condon 2006.

Sample Preparation

As vials for BET analysis are often extremely narrow at the opening, it is imperative that care be taken not to damage or alter the sample during loading. This is especially true for porous materials which may be collapsed if pressure is applied and brittle systems which may fracture during loading. Fracture may yield inaccurate higher surface areas, while collapse results in substantially reduced values.

Degassing

The removal of gases and vapors physically adsorbed onto the surface of the powder being tested, termed degassing, is essential prior to determining the specific surface area (SSA, i.e., m^2/g) of any sample. Failure to do so may result in a reduction in the calculated surface area or a high variability in obtained SSA values (USP 32–NF 27 General Chapter 846). It has been suggested that an adsorbed impurity will not alter the BET surface area calculation, provided its boiling point is at least three times higher than the adsorption temperature (Joy 1953). However, such impurities may influence the calculated heat of adsorption (C-value). Therefore, in order to ensure accurate, reproducible surface area measurements, proper sample preparation must be employed.

Due to factors such as temperature sensitivity, variations in surface energies, particle sizes, and porosity, no single method may be applied universally that guarantees complete removal of adsorbed gases and vapors to the powder surface; however, two methods are often applied: vacuum pumping and purging by use of an inert gas (Lowell and Shields 1991).

When applying a vacuum, a pressure of 10^{-5} Torr has been stated as sufficient in outgassing procedures. The application of elevated temperatures will increase the rate at which impurities/contaminants leave the powder surface, reducing the time required to hold the vacuum (Fagerlund 1973). However, heat-labile products must be monitored with care, and glass vessels used in most BET equipment have a threshold of 400°C (Igwe 1991). Additionally, elevated temperatures may cause rapid water loss from the sample surface, resulting in altered morphology or sample collapse. Samples that are sensitive to heat should be degassed at ambient temperatures

under vacuum for long periods of time, such as 12–24 h, in order to reach constant weight (Lowell and Shields 1991; Engstrom et al. 2007).

Alternatively, flushing the powder sample with an inert gas may also be used to clean the surface. This purge gas must be of extremely high purity and dry so as not to introduce contaminants or induce moisture-related phenomena such as crystallization. Heat may also be provided in this method as well to aid in desorption (Sing et al. 1985). For samples in which heat may not be applied, multiple absorption–desorption cycles may be employed to clean the surface with three to six cycles providing sufficient cleanliness for reproducible measurements (Dios Lopez-Gonzalez et al. 1955). This may also be done using gas blends such as nitrogen (10% v/v) in helium (Pendharkar et al. 1990).

Regardless of the chosen degassing method, the sample must be monitored by some means to ensure degassing is complete. With regard to vacuum pumping, literature often describes the method of ensuring all adsorbed gases and vapors are removed as monitoring of the system pressure. Webb and Orr (1997) state that isolated samples displaying a pressure rise of $<10^{-3}$ Torr/minute are indicative of adequate degassing. Similarly, Gregg and Sing (1982) state a pressure of 10^{-4} Torr as sufficient, while Sing states ~ 10 MPa is satisfactory (Gregg and Sing 1982; Sing et al. 1985). Allen (1997) states outgassing to be complete if, following 15 min of isolation from the vacuum, no pressure increase is observed upon reintroduction to vacuum, while Igwe deems completion as maintaining a pressure between 10^{-4} and 10^{-5} mmHg for a substantial period of time following isolation from the pumping line and cold trap (Igwe 1991; Allen 1997).

As mentioned earlier, purging with an inert gas may be used to clean the sample. In this case, the effluent gas may be monitored via mass spectroscopy, or a thermal conductivity detector which may detect impurities in the range of a few parts per million (ppm). Once the level of contaminants and foreign material is below detection, adequate removal of the adsorbed material has been achieved (Sing et al. 1985; Lowell and Shields 1991).

Again, no single method can be employed universally to properly degas a sample prior to analysis. Understanding the morphology (i.e., porosity) and thermal sensitivity of a powder will aid in determining degassing time and temperature as a more porous network will require increased times. However, once a sample has been run under a given set of parameters, it is recommended that a second sample be run using an extended degassing time (i.e., 1.5–2 \times the original time). If the results are statistically significantly different, the first results may be discarded and the second set of parameters selected. Additionally, it is recommended that powders be analyzed at least in triplicate using three individually prepared samples, especially for powders with a large particle-size distribution.

Sample Analysis

Prior to any sample analysis, the BET unit to be used should be properly calibrated for accurate results. This can be performed using commercial reference standards

such as silica, garnet, or kaolinite (Antila and Yliruusi 1991). These can most readily be purchased from the manufacturer of the equipment in use, such as the alumina pellets offered by Quantachrome, and range in SSA values from below 1 to greater than 150 m²/g. Standard selection will depend upon the samples to be analyzed, as the standard SSA should be near that of the samples. For example, Swinkels et al. (1994) used a kaolinite reference standard with a specific surface area of 16.2 m²/g to verify that no drift had occurred prior to sample analysis of the experimental samples (SSA 26–32 m²/g).

Following calibration, sample analysis can be performed. As mentioned earlier, care must be taken when adding the sample to the analysis bulb and the weight of the added powder must be known. The analysis bulb should be weighed empty on an analytical balance, the powder then added, and the final weight of the bulb measured and recorded. Subtraction of the bulb weight from the final weight of the filled bulb allows accurate determination of the true amount of sample added. The amount of powder added will depend on density, as most commercial BET units require a minimum surface area rather than minimum weight. For example, the Nova[®] Series offered by Quantachrome requires a minimum of 0.01 m² for accurate analysis. While sample sizes may be low for high surface area powders such as those produced by spray freezing into liquid (200 mg (Rogers et al. 2002)), higher amounts are necessary for lower surface area materials (5 g (Swinkels et al. 1994)). Sample degassing can then be performed utilizing the appropriate method from those outlined above. Post degassing, the weight of the sample should again be taken to ensure accuracy when calculating SSA as some weight will be lost during the degassing process (Sing et al. 1985). Analysis is then carried out with nitrogen often used as the adsorptive gas; however, for powders exhibiting extremely low SSA values it is necessary to use an adsorptive gas of lower vapor pressure. In such cases, krypton can be employed. It must be noted that differences in SA values will be obtained based on the gas used for the study as the size of the gas molecules forming the monolayer will differ resulting in differences in pore penetration (Sandell 1993).

During analysis, the sample is repeatedly lowered into a liquid nitrogen bath. While this process is automated by today's units, the researcher is still required to maintain the level of liquid nitrogen in the Dewar to ensure proper submergence of the sample; failure to do so will result in inaccurate results. Data reduction can then be performed and the results reported as m²/g material.

2.2.5 Residual Solvent Analysis

Many synthesis processes as well as formulation production processes used for PWS drugs such as spray drying, roto-evaporation, precipitation methods, and freeze-drying methods require the use of various organic and inorganic solvents. The physicochemical properties of the material in use such as crystallinity have proven to influence the amount of residual solvent levels within the product (Witschi and Doelker 1997) As many of these solvents are highly toxic, it is imperative that

they be present only at extremely low levels, if at all, in the final product so as to reduce the risk to the end user. The following sections discuss residual solvent acceptance limits as well as methods for determination of residual solvents present in final products.

2.2.5.1 Residual Solvent Guidelines

The primary concern for residual solvents in pharmaceutical products is organic volatile impurities (OVIs). ICH guideline Q3C (R4) from February 2009 categorizes OVIs into three classes: class 1 includes solvents that are known or suspected human carcinogens as well as environmental hazards; class 1 solvents should be avoided if possible. Class 2 solvents include solvents that are nongenotoxic animal carcinogens or possible causative agents of irreversible toxicity (i.e., neurotoxicity) as well as significant but reversible toxicities; class 2 solvents are to be limited in final formulations. Class 3 solvents are solvents with low toxic potential to man such that no specific exposure limit is required; class 3 solvents have permitted daily exposure levels of 50 mg or more per day. Table 2.3 outlines prevalent class 1, 2, and 3 solvents used in pharmaceutical preparations. It should be noted that these residual solvent guidelines do not apply to new chemical entities, excipients, or drug products during clinical research stages of development (Dwivedi 2002).

2.2.5.2 Analytical Determination of Residual Solvent Levels

If only class 3 solvents are used during production, nonspecific methods such as loss on drying may be used for quantitation of residual solvent. This includes LOD apparatus analysis as well as TGA described above. When class 1 or 2 solvents have been used, their residual levels must be quantitated by a specific means. The USP 32/NF 27 specifies gas chromatography with flame-ionization detection (GC-FID) as the preferred method of detection and quantitation. Additionally, it is specified that a 0.32 mm × 30 m fused-silica column coated with a 1.8- μ m layer of phase G43 be used for analysis. This may be substituted with a 0.53 mm × 30 m wide-bore column coated with a 3.0- μ m layer of phase G43. Carrier gasses of nitrogen or helium are acceptable. It is stated that the column temperature be maintained at 40°C for 20 min and then raised at 10°C/min to 240°C. This temperature is then held for 20 min. Injection port and detector temperatures of 140°C and 250°C are specified, respectively. Additional methods such as GC-mass spectroscopy have been employed; however, due to the low molecular weights of many of the listed solvents such methods have proven difficult and only qualitative with quantitation limited (Mulligan and McCauley 1995; Pavon et al. 2006).

The USP provides reference standard solutions for class 1 and 2 solvents (USP Class 1 Residual Solvents Mixture RS and USP Residual Solvents Class 2–Mixture A RS) which can be used for system optimization and method development.

Table 2.3 Residual solvent levels in pharmaceutical products.
Reproduced from ICH Guideline Q3C (R4)

| Solvent | Concentration limit (PPM) |
|-------------------------|---------------------------|
| <i>Class 1 solvents</i> | |
| Benzene | 2 |
| Carbon tetrachloride | 4 |
| 1,2-dichloroethane | 5 |
| 1,1-dichloroethene | 8 |
| 1,1,1-trichloroethane | 1,500 |
| <i>Class 2 solvents</i> | |
| Acetonitrile | 410 |
| Chlorobenzene | 360 |
| Chloroform | 60 |
| Cyclohexane | 3,880 |
| 1,2-dichloroethene | 1,870 |
| Dichloromethane | 600 |
| 1,2-dimethoxyethane | 100 |
| N,N-dimethylacetamide | 1,090 |
| N,N,-dimethylformamide | 880 |
| 1,4-Dioxane | 380 |
| 2-Ethoxyethanol | 160 |
| Ethyleneglycol | 620 |
| Formamide | 220 |
| Hexane | 290 |
| Methanol | 3,000 |
| 2-Methoxyethanol | 50 |
| Methylbutyl ketone | 50 |
| Methylcyclohexane | 1,180 |
| N-Methylpyrrolidone | 530 |
| Nitromethane | 50 |
| Pyridine | 200 |
| Sulfolane | 160 |
| Tetrahydrofuran | 720 |
| Tetralin | 100 |
| Toluene | 890 |
| 1,1,2-trichloroethene | 80 |
| Xylene | 2,170 |
| <i>Class 3 solvents</i> | |
| Acetic acid | Heptane |
| Acetone | Isobutyl acetate |
| Anisole | Isopropyl acetate |
| 1-butanol | 3-Methyl-1-butanol |
| Butyl acetate | Methylethyl ketone |
| Tert-butylmethyl ether | Methylisobutyl ketone |
| Cumene | 2-Methyl-1-propanol |
| Dimethyl sulfoxide | Pentane |
| Ethanol | 1-Pentanol |
| Ethyl acetate | 1-Propanol |
| Ethyl ether | 2-Propanol |
| Ethyl formate | Propyl acetate |
| Formic acid | |

Headspace analysis is the preferred sampling technique for GC analysis. In headspace analysis, the sample for analysis is placed in a sealed vial and equilibrated at elevated temperatures. The temperatures must be high enough to allow for evolution of the bound solvent without combustion or damage to the material under analysis, especially for materials which evolve gasses upon decomposition. An aliquot of the evolved gas phase is then injected for analysis. During sample preparation, it is often necessary to grind the powder such that the internal area of the formulation is exposed. This process, however, can lead to solvent evolution, thereby leading to inaccurately low results and care must be taken during preparation to prevent this.

A novel liquid-phase extraction method was developed by Liu and Jiang (2007). Using the PWS drug adefovir dipivoxil solutions were prepared by adding 100 mg of API to a 5-mL headspace vial. The ionic liquid 1-butyl-3-methylimidazolium tetrafluoroborate (bminBF_4) was then added to each vial (2 mL) and the material dissolved. The vials were then crimp sealed and placed in an autosampler for analysis. GC-FID was employed for analysis of all samples. Indeed, all six analyzed solvents could be identified, making the method ideal for materials which are PWS and poorly soluble in organic solvents often used for liquid-phase extraction such as DMSO and toluene.

2.3 Stability Testing

Development of PWS drugs often relies on the use of an altered drug form such as a less stable but more soluble polymorph or the amorphous form of the compound. While each of these solutions may enhance aqueous solubility, they bring with them numerous stability issues such as conversion to a more stable polymorph, recrystallization of the amorphous material, or reduced chemical stability. Indeed, conversion to a different polymorph may yield drastic reductions in solubility or complete loss of therapeutic activity. These conversions can be exasperated in the presence of excipients or by the environmental conditions of the region for distribution (Bott and Oliveira 2007). As such, it is necessary to gain a detailed understanding of the stability of the drug itself as well as all potential formulations throughout the development cycle.

2.3.1 Stability Monitoring

For stability studies of an API or formulation such as those outlined in the following sections, samples are to be taken at designated time points throughout the study and the formulations analyzed for any significant changes. These changes may arise as loss of potency, the formation of impurities, alterations in drug form, moisture uptake, or changes in dosage form performance (i.e., dissolution profile, color, hardness, leakage, brittleness, and pellicle formation), and can be monitored by the solid-state characterization methods described in previous sections or alternative

analytical methods. Formulations that may uptake significant amounts of moisture should be analyzed for moisture content by loss on drying (LOD) studies or Karl Fischer titration (Williams et al. 2004). Karl Fisher titration of PWS drugs can be performed by dissolving a known amount of the compound in anhydrous methanol and analyzing the solution. Alternatively, the powder for analysis can be added directly to the titration vessel, provided it dissolves in the media therein (Rogers et al. 2002). Thermally liable substances are likely to be damaged by standard LOD testing (typically 105–130°C). For such a material, LOD studies should be conducted at ambient temperatures in the presence of strong desiccants (Bizzi et al. 2011). For all of these studies, a deviation of 5% from initial value following storage is considered significant. While dissolution-testing parameters should be based on USP general chapter 711, solid-state characterization methods must be optimized for the formulation at hand as described above to ensure adequate assessment of stability.

Validation or development of analytical methods capable of detecting impurities or degradation products is essential for new formulations or new chemical entities. Oftentimes, such method development will be performed concurrently with the chemical stability studies outlined below. Selective methods include but are not limited to high-pressure liquid chromatography (HPLC), thin-layer Chromatography (TLC), gas chromatography (GC), liquid chromatography mass spectroscopy (LCMS), gas chromatography mass spectroscopy (GCMS), and Raman spectroscopy. Reflectance spectroscopy has proven useful for determining changes in the appearance and color of solid dosage forms. This process may also be sufficiently selective in isolated cases to be used for degradation quantitation (Stark et al. 1996). The method selected must be capable of separating the drug from degradation products as well as from excipients used during formulation. HPLC is perhaps the most widely employed analytical method for stability-indicating assays. Belal et al. developed a reverse-phase HPLC method for quantification of quetiapine as well as its two degradation products, quetiapine N-oxide and quetiapine lactam. Chromatographic conditions included a mobile phase composed of acetonitrile and 0.02 M phosphate buffer (50:50) at pH of 5.5 with a flow rate of 1 mL/min and detection at 254. Separation was achieved using a 250 mm×4.6 mm i.d., 5- μ m particle-size Zorbax SB-Phenyl column. This method proved sufficient for quantification of drugs and degradation products in both tablets and human plasma samples. For additional examples of stability-indicating assay method development, especially regarding HPLC, the reader is referred to Cuiping et al. (1993), Stanisz and Kania (2006), Ahuja and Rasmussen (2007), Belal et al. (2008), and Corrandini and Phillips (2011).

2.3.2 *Chemical Stability*

Prior to studying formulations of a given compound, it is imperative that the raw drug components stability be assessed. While the above-mentioned analytical

techniques such as DSC and TGA can be used to identify degradation or transitions at elevated temperatures, the influence of moisture is absent from these studies. As such, suspensions of the PWS drug under study should be prepared at multiple pH values similarly to the solubility studies previously described and analyzed for degradation, polymeric conversions, recrystallization of amorphous material, and the dissociation of salt forms of APIs. For a detailed understanding of potential reaction pathways and kinetics thereof, the reader is referred to Waterman and Adami 2005. For example, the two metastable polymorphs of mebendazole were studied to understand the interconversion between polymorphic forms in the following manner: 500 mg of the polymorphs were placed in glass vials, half of which also contained water, the vials sealed and placed at 5, 50, or 100°C. Samples were removed at predetermined time points over a 75 h period and analyzed by XRD and DRIFT-IR for transformations. Indeed, it was found that in the absence of moisture even elevated temperatures of 100°C did not induce crystal transformations. However, the samples containing drug suspended in water at elevated temperatures demonstrated partial conversion of form B to C after 25 h. Additionally, it was found that suspensions of form C stored at 100°C converted entirely to form A within 50 h (Brits et al. 2010). A lack of understanding of such phenomenon can lead to processing difficulties during development. For example, dissociation of the salt form of an API to the free base can occur upon moisture uptake or introduction to the system. Using in line Raman spectroscopy, it was shown that the extended exposure to moisture during the wet granulation process employed prior to tableting of an experimental compound led to significant dissociation of the hydrochloride salt yielding the free base (Williams et al. 2004).

The ICH has set forth multiple guidelines regarding stability testing of APIs. Photostability studies must expose samples to an overall illumination of ≥ 1.2 million lux hours and ≥ 200 W h/m² of near-UV energy. Control samples protected by aluminum foil or a similar means must be placed next to the exposed samples to ensure authenticity (ICH guideline Q1B). Following the ICH guidelines, the photostability of fexofenadine hydrochloride was assessed via exposure to 1,800 W h/m² of UV light and demonstrated a reduction in potency of 43% (Bhalekar et al., 2010). The ICH also outlines stress-testing requirements for determination of potential degradation pathways, including acidic/alkali degradation, oxidative degradation, and thermal degradation (ICH guideline Q1A). Such studies can be conducted on drug powders, suspensions, or solutions. Valsartan and amlodipine were studied for these four degradation pathways in the following manner: 1 mL of 0.1 M HCl (acidic degradation), 0.1 M NaOH (alkali degradation), or 3% H₂O₂ was added to 9 mL of drug solution (final concentration: 16 µg/mL) and allowed to stand at ambient conditions for 24 h. A solution of identical concentration in water was placed at 50°C and allowed to stand for 24 h. Following the 24 h period, samples were analyzed by a validated HPLC method for degradation products. Results demonstrate that valsartan degraded at elevated temperatures and in the presence of hydrogen peroxide, while amlodipine was degraded under all conditions (Chitlange et al. 2008). Ezetimibe was placed under similar stress conditions; however, in order to achieve a desired 0.5 mg/mL solution 30% acetonitrile was

added to each vial under study (final solution 70:30 H₂O:ACN). In this case, the acidic (0.1 M HCl), neutral (water), and alkali (0.1 M NaOH) solutions were heated to 80°C and held for 8 h to reduce the duration of the study. This was repeated at 40°C as well. Oxidative studies were carried out under 3 and 20% hydrogen peroxide solutions at room temperature for 24 h. Photodegradation was assessed in water and 1 M HCl by exposing the solutions to sunlight for 2 days (60,000–70,000 lx). In this study, the bulk drug powder was also studied for thermal liability via exposure to dry heat: 50°C for 45 days and 60°C for 7 days. These studies revealed the primary degradation pathway to be alkaline hydrolysis (Singh et al. 2006). Knowledge of the potential degradation pathways of an API will greatly aid the formulation scientist ensuring processes which may induce degradation are avoided. Studies such as these should be carried out concurrently with or prior to solubility studies to ensure that the solubility values obtained are not skewed by degradation.

2.3.3 *Stability Testing Conditions*

Stability testing of potential formulations of an API must be performed to understand the synergistic influence of environmental conditions and time on the dosage form. Indeed, a stable API can become unstable in the presence of another material as exemplified in the carbamazepine:stearic acid example provided in the section regarding XRD, or in the presence of moisture or elevated temperatures as shown above (Bott and Oliveira 2007).

The ICH has set guidelines (ICH Q1A (R2)) for stability testing of formulations relative to the intended storage conditions upon distribution as well as geographical region for distribution. This includes products intended for storage at room temperature, in a refrigerator, or in a freezer. Table 2.4 outlines the storage conditions to be used for short term, long term, and accelerated stability tests based on the intended storage location of the final product. Long term studies must be conducted on three primary batches if an NDA is to be filed and must cover a 12 month period. If the proposed shelf life is greater than 12 months, the stability study must be continued for the duration of the expected shelf life. Accelerated conditions are often employed during preformulation studies as the timeline is significantly shortened; however, such a study is supplemental to and does not replace the long term storage data. Indeed, the elevated conditions of accelerated stability testing can induce changes which may not occur under normal storage. If any significant change occurs over the 6 month storage period at accelerated conditions, an intermediate study must be conducted as well (Gad 2008).

Tests should be carried out in the container identical to that intended for distribution. This has led to a revision of the proposed conditions for stability testing to include conditions for semipermeable containers. In this case, testing temperatures are identical to those provided in Table 2.4; however, relative humidity values are altered such that long term storage is carried out at 40% RH (35% RH if 30°C is

Table 2.4 Stability testing conditions for products with various intended storage conditions

| Stability study type | Stability storage conditions | Minimum time period covered by data at submission (months) |
|---|---|--|
| Marketed API intended for room-temperature storage conditions | | |
| Long term | 25°C ± 2°C/60% RH ± 5% RH or 30°C ± 2°C/65% RH ± 5% RH | 12 |
| Intermediate | 30°C ± 2°C/65% RH ± 5% RH | 6 |
| Accelerated | 40°C ± 2°C/75% RH ± 5% RH | 6 |
| Marketed API intended for storage in refrigerator | | |
| Long term | 5°C ± 3°C | 12 |
| Accelerated | 25°C ± 2°C/60% RH ± 5% RH | 6 |
| Marketed API intended for storage in freezer | | |
| Long term | -20°C ± 5°C | 12 |

selected for testing), intermediate testing is set to 65% RH, and accelerated conditions employ no more than 25% RH.

For systems that are amorphous, the T_g of the formulation must be strongly considered when selecting testing conditions. Indeed, accelerated conditions may employ temperatures near or above the T_g of a product, yielding alterations in physical form and complicating data interpretation. Improper selection of temperatures at or above the T_g of a system may lead to under-prediction of the shelf life of a product (Duddu and Weller 1996). Amorphous systems which have a high T_g however do not necessitate the selection special conditions and can be studied under the accelerated conditions outlined in Table 2.4 (Lakshman et al. 2008).

Following development of indomethacin into coprecipitates and solid dispersions with Eudragit® polymers with subsequent tableting of the formulations stability studies were conducted at -20, 4, 37, 45, and 55°C with relative humidity values of 11, 51, and 91%. Tablet samples were removed from storage at intervals of 1 month over a 6 month period and tested for transformations by XRD and DSC as well as for changes in dissolution profiles using rotating basket dissolution apparatus. Indeed, storage at extremely low temperatures as well as elevated temperatures in a humid environment slowed down dissolution rates of the drug (Khan et al. 2000). Solid-state characterization demonstrated that this was likely due to an increase in crystallinity of the product. A similar study utilized 10 tablets per container with two containers per storage condition (4, 25, 37, 45, 55°C, and 37°C with 11, 51, and 91% RH). Nine tablets were removed at time points of 0.5, 1, 3, 6, 9, and 12 months and characterized by XRD and DSC and tested for dissolution properties (Goskonda et al. 1998). Tablets however may not be the intended final formulation as is the case with solid dispersions which can be filled into capsules. In this instance, the formulation should be assessed for stability in powder form. For example, DiNunzio et al. placed 2 g of solid dispersion powder into 30-mL high-density polyethylene bottles which were then induction sealed. Samples were placed under accelerated storage conditions (40°C, 75% RH). At time intervals of 1, 3, and 6 months, samples were removed and tested for crystallinity. The samples were allowed to equilibrate to room temperature for 24 h prior to analysis. It was shown

that formulations containing a plasticizer ($T_g = 54^\circ\text{C}$) exhibited recrystallization under accelerated conditions while formulations lacking the plasticizer ($T_g = 101^\circ\text{C}$) did not (DiNunzio et al. 2010a).

2.4 Dissolution Testing

As mentioned earlier, BSC Class II APIs are limited in their bioavailability based on their dissolution rate or extent. Therefore, many formulators attempt to overcome this barrier by generating systems capable of achieving solubilization significantly higher than the intrinsic solubility of the compound (i.e., supersaturation). The ability to achieve supersaturation in physiologically relevant medias can indeed be a strong indicator of enhancement of bioavailability. However, this can only truly be confirmed by transitioning optimized formulations into animal models.

Dissolution studies are often carried out under sink conditions; however, for many PWS drugs such conditions cannot be met due to the extremely high volumes of dissolution media that would be required. As such, studies using sink conditions will not be discussed; rather, the focus of the following sections will be on supersaturation studies and in vivo studies of optimized formulations

2.4.1 Dissolution Studies

2.4.1.1 Sample Handling

During dissolution testing, samples will be taken at various time points to assess drug release from and supersaturation ability of the formulation. Proper handling of these samples ensures accuracy in the assay used to assess drug in solution. Filtration is a widely used technique for removing undissolved materials, both drug and insoluble excipients, from the analytical sample. This is done by placing a withdrawn dissolution sample in a syringe and passing through an attached syringe filter. Filter sizes often used in literature are $0.45\ \mu\text{m}$, $0.22\ \mu\text{m}$, and $0.1\ \mu\text{m}$, with the syringe size selected based on the withdrawn sample size. A wide variety of filter membrane materials exist for this application, including but not limited to nylon, hydrophilic and hydrophobic polytetrafluoroethylene (PTFE), polyvinylidene fluoride (PVDF), and cellulose such as cellulose acetate (Okazaki et al. 2008; Ferrari et al. 2009; Tho et al. 2010; Xia et al. 2010).

Prior to use in dissolution studies, it is important to assess filter membrane compatibility with the API and sampling solution. Indeed, drug adsorption to the filter membrane can lead to inaccurately low results. Additionally, membrane degradation in the presence of solvents used may allow the passage of undissolved drug into the analytical sample which may dissolve upon dilution, yielding inaccurately high results. To validate a filter, an API stock solution of known concentration is

prepared in the media(s) to be used during dissolution testing. Aliquots of the stock solution are then filtered and diluted and compared to a diluted unfiltered sample. If the filtered sample displays 98–102% recovery of the API, the filter is considered acceptable (Fortunato 2005). Such a method was employed for dissolution studies of the PWS lamotrigine. A stock solution of lamotrigine was prepared at a concentration of 11 $\mu\text{g}/\text{mL}$ in 0.1M hydrochloric acid. The solution was sonicated for 15 min in a sonication bath to ensure complete dissolution of the API. A 4-mL aliquot of the stock solution was then diluted with 0.1M HCl to a final volume of 20 mL in a volumetric flask as an unfiltered control. The remaining solution was passed through the filter under study and a 4-mL aliquot of the filtrate diluted to 20 mL with 0.1M HCl. UV spectroscopy of the filtered and nonfiltered samples revealed less than 2% variability between the solutions, indicating the filter was acceptable (Martins et al. 2010). Although not a PWS API, a study of three potential filters and three potential dissolution medias (0.01, 0.1M HCl, and pH 6.8 phosphate buffer) to be used during dissolution testing of citalopram was conducted in a similar manner. The analysis revealed that the quantitative and 0.45- μm nylon filters were acceptable for use during dissolution studies while the 3- μm filter under study was not (Menegola et al., 2007). This method was also used in filter evaluation for dissolution studies on the BSC Class IV compound entacapone. In this iteration, 50 mL of stock solution was prepared in the dissolution medium at a concentration of 44.44 $\mu\text{g}/\text{mL}$. Complete dissolution was ensured by sonication for 30 min in a sonicating bath. Samples were then filtered through quantitative and nylon filters and compared to an unfiltered diluted sample. It was found that both filters were within the limits of acceptance for use during the studies. Additionally, it was shown that the quantity of methanol to be used for dilution did not alter the filter functionality (Paim et al. 2010).

In addition to membrane filter-type selection, the appropriate pore size must be selected based on the formulation at hand. Following solubility studies of fenofibrate in bio-relevant medias, Juenemann et al. analyzed the dissolution of nanosized formulations of the API. Filters of various pore sizes were assessed and the 24 h fenofibrate concentrations obtained via dissolution studies were compared to the 24 h solubility study data. It was shown that pore sizes of 0.45 or 0.2 μm yielded concentrations higher than those obtained during solubility studies, while pore sizes of 0.1 μm or less generated concentrations similar to those of the solubility studies. Indeed, the colloidal fenofibrate was too fine to be withheld by filters of larger pore sizes which, upon sample dilution with solvents, resulted in apparent supersaturation (Juenemann et al., 2011).

If adequate recovery cannot be achieved via filtration, samples may be centrifuged instead and the supernatant sampled for analysis. In the above-mentioned study regarding lamotrigine, a stock solution was centrifuged at 3,000 rpm for 10 min. A 4-mL aliquot of the supernatant was then diluted to 20 mL in dissolution media. The remaining supernatant was filtered and a 4-mL aliquot of the filtrate diluted to 20 mL in dissolution media. Samples were analyzed via UV spectroscopy and revealed less than 2% variability. This confirms the acceptance of the filter to be used as well as the potential for centrifugation in place of filtration.

While centrifugation may be used as a reference during filter analysis, it can also be used for sample purification in place of filtration. This can be employed when an acceptable filter cannot be identified due to membrane interactions (Fortunato 2005). To ensure adequate sedimentation of all particulates present, high-speed centrifugation is employed. For example, centrifugation at 14,000 rpm for 10 min was used for dissolution sample preparation for capsule dissolution studies of an experimental compound (Zhao et al. 2009). Dissolution studies performed directly in the centrifuge tube (discussed below) have been subjected to rotation at 13,000 g for 1 min prior to sampling to ensure adequate sedimentation (Friesen et al. 2008).

2.4.1.2 Excipient Screening for Supersaturation Maintenance Ability

The ability to achieve supersaturation is highly promising with regard to increasing bioavailability. However, the ability to maintain supersaturation can prove even more beneficial. APIs with pH-dependent solubilities may rapidly precipitate from solution upon transition from the stomach to the intestine. Therefore, prevention of this formulation collapse may allow greater time for absorption and increased bioavailability. A novel approach in the screening of excipients capable of maintaining supersaturation has been presented by Vandecruys et al. (Vandecruys et al. 2007). In this method, various excipients of interest were dissolved at a level of 2.5% w/v in 10 mL of the corresponding medias of interest: 0.01H HCl, USP pH 4.5 buffer, USP pH 6.8 buffer or water. Separately, various drugs of interest were dissolved at a concentration of 50–100 mg/mL in N,N-dimethylformamide (DMF) or dimethylacetamide (DMA). For a given test, the desired dissolution media containing the excipient to be studied was placed under magnetic stirring and equilibrated to 37°C. The selected API solution was then added drop-wise to this stirring media until a precipitate was just noticeable visually. Samples were then taken at 5, 30, 60, and 120 min following the completion of drug addition, filtered, and analyzed for drug content via UV spectroscopy. Application of this method to excipient blends may allow for an even deeper understanding of the formulation requirements for the maintenance of supersaturation.

The above method was adapted in the screening of various HPMC grades for their ability to supersaturate itraconazole in neutral media (intrinsic solubility ~1–5 ng/mL). In this iteration, 75 mg of the excipient was dissolved in 1 L of pH 6.8 phosphate buffer. Itraconazole was separately dissolved in 1,4-dioxane at a concentration of 18.75 mg/mL. Following equilibration of the dissolution media to 37°C, a 2-mL aliquot of the itraconazole solution was added to the dissolution vessel and samples were withdrawn at 5, 10, 15, 30, 45, 60, 90, 120, 180, 240, and 1,440 min. Withdrawn samples were immediately passed through a 0.2- μ m filter and diluted 1:1 with mobile phase (70:30:0.05 acetonitrile:water:diethanolamine) and subsequently analyzed for itraconazole concentration via HPLC (DiNunzio et al. 2010a, b, c). Application of the method identified HPMCAS grades as the most promising and these polymers were subsequently used in the production of solid dispersions.

2.4.1.3 Supersaturation Dissolution Studies

Following production of lead formulations, their ability to achieve supersaturation must be assessed. This can be accomplished by adding an amount of formulation to a dissolution vessel such that the amount added contains an excess amount of drug relative to the intrinsic solubility, thereby, upon complete dissolution, a theoretical level of supersaturation is achieved. For example, in a study of HME itraconazole formulations, 180 mg of milled extrudate (containing 60 mg itraconazole) was added to each dissolution vessel. Assuming complete dissolution, this amount corresponds to 80 $\mu\text{g/mL}$ representing 20 \times supersaturation (intrinsic solubility under acidic conditions: 4 $\mu\text{g/mL}$) (Miller et al. 2008). A similar work employs itraconazole at a level equivalent to 10 \times equilibrium solubility (DiNunzio et al. 2010a, 2010b, 2010c). In a separate work, 7 mg of tacrolimus formulations were added to 100 mL small-volume dissolution vessels containing acidic media corresponding to 28 \times the equilibrium solubility of the native API (Overhoff et al. 2008). Using identical conditions, the ability to maintain supersaturation upon pH transitions was assessed by transitioning the pH of the dissolution media to 6.8 via addition of appropriate amounts of 0.2M Na_3PO_4 .

Such studies are not limited to supersaturation of GI media. Using simulated lung fluid containing 0.02% dipalmitoylphosphatidylcholine and small volume (100 mL) dissolution vessels, 100 μg of itraconazole in a colloidal dispersion corresponding to 100 \times equilibrium solubility was added in the assessment of a nanosized formulation for inhalation. In fact, it was shown that the formulation was capable of achieving 27 \times supersaturation versus crystalline itraconazole (Yang et al. 2008).

Of crucial importance to each of these studies is the prevention of precipitation in the withdrawn samples, which can lead to inaccurately low results, as well as accidental solubilization of withdrawn particulates yielding positive deviations. To prevent these occurrences, withdrawn samples must be treated immediately upon withdrawal as discussed above and diluted with an appropriate organic solvent, such as the mobile phase employed in the aforementioned screening studies. Analysis of the diluted samples via a specific method such as HPLC can be utilized on the diluted samples and the determined concentration adjusted for dilution via minor calculations.

Additional methods not employing a dissolution apparatus have also been used in supersaturation dissolution testing. Curatolo et al. developed two novel approaches for supersaturation testing. In the first method, 7.5 mg of a formulation was placed in an empty disposable 10-mL syringe. A 20-gauge needle was attached and used to draw 10 mL of model fasted duodenal fluid at 37°C into the syringe. The needle was then removed, a 13 mm, 0.45- μm filter was attached, and the syringe shaken for 30 s. Six drops were then expelled as waste followed by collection of 13 drops as a sample. The plunger was then pulled back to introduce an air bubble and promote mixing, and the syringe with attached filter was placed on a rotating wheel in a temperature-controlled box held at 37°C to mix. Sampling was then repeated in the identical manner at various time points. All samples were diluted with mobile phase to prevent precipitation.

In a second method by the same group, 1.8 mg of the formulation was placed into an empty microcentrifuge vial and 1.8 mL of model fasted duodenal fluid added. The tube was then vortex mixed for 60 s and then allowed to stand for 6 min without disruption. Following the equilibration period, the sample was centrifuged at 13,000 *g* for 60 s. A sample of the supernatant was then taken. Following sampling, the vial was vortexed for 30 s to resuspend the material and allowed to stand for a designated period of time. At the next set time point, the material was again centrifuged and sampled as described previously (Curatolo et al. 2009). All samples were diluted 1:1 with mobile phase upon withdrawal to prevent precipitation. No filtration was applied as centrifugation removed all particulate matter from the sampling media.

2.4.1.4 Alternative Dissolution Studies

The use of bio-relevant dissolution medias such as simulated lung, gastric, and intestinal fluids may provide stronger *in vitro*–*in vivo* correlations and more accurate predictions of formulation performance. However, the use of such fluids introduces new molecular variables into solution. For example, fasted-state-simulated gastric fluid comprises sodium taurocholate, lecithin, pepsin, sodium chloride, and hydrochloric acid, while simulated the lung fluid previously mentioned contains 0.02% dipalmitoylphosphatidylcholine (Vertzoni et al. 2005). A detailed discussion including instructions on the preparation of various simulated intestinal fluids can be found in Jantratid et al. 2008. Two concerns are raised during the use of such dissolution media. First, upon dissolution multiple species may form in solution. Friesen et al. describes seven potential species based on size that may form upon dissolution of a polymeric formulation in such media. These include free/solvated drug, drug in bile-salt micelles, free/solvated polymer, polymer colloids, amorphous drug/polymer nanostructures, small aggregates of amorphous drug/polymer nanostructures, and large precipitates (Friesen et al. 2008). As the free drug is the primary absorbed species and of chief concern during dissolution studies such systems require unique handling during drug analysis to ensure that there is no interference from undesired components. Filtration, as described above, has proven sufficient in separating undissolved drug from simulated fasted-state intestinal fluids and certain gastric fluids. However, more complex medias may require additional steps. For example, a study in milk-based media required preliminary filtration of undigested samples through a 5.0- μm nylon filter followed by dilution with acetonitrile (protein precipitation), centrifugation at 4,000 rpm for 10 min at 8°C, and final filtration of the supernatant through 0.45- μm regenerated cellulose filters. Similarly, digested samples were first centrifuged under the above conditions to separate the aqueous phase from not only the undissolved drug but also the digested and lipid phases. Aqueous phase samples were then diluted with acetonitrile and recentrifuged with subsequent filtration through the aforementioned 0.45- μm regenerated cellulose filter (Fotaki et al., 2005). It should also be noted that lipid-based formulations require centrifugation to remove nonemulsified lipid droplets prior to aqueous phase sampling (Jantratid et al. 2008).

The implementation of dialysis methods for dissolution studies minimizes the need for sample handling. As dialysis membranes with specified molecular weight cutoffs can be used such that only solubilized drug is able to pass through, subsequent filtration or centrifugation is not required. It is recommended that filtration still be carried out on samples, however, to remove any potential external contaminants such as dust which may enter the sampling media during lengthy studies. Dialysis dissolution has been used on micellar solutions of paclitaxel (molecular weight cutoff of 3,500) by loading the membrane bag with the solution and placing it in 20 mL of phosphate-buffered saline (pH 7.4). The media was held at 37°C and agitated by an orbital shaker at 160 rpm. Sampling was performed by complete dissolution media removal and replacement with fresh PBS. Dissolution was allowed to continue for 30 days (Yang et al. 2009). Similarly, 5 mL of a suspension of chitosan nanoparticles in pH 7.4 buffer was placed in a dialysis bag and placed in pH 7.4 buffer reception media. Agitation by orbital shaking (110 rpm) was applied and samples were taken at predetermined time points by complete media replacement (Syam et al. 2010). It should be noted that dialysis methods may require equilibration periods depending on the formulation. Indeed, drug nanoparticles placed in a dialysis bag exhibited significantly lower dissolution rates compared to basket and paddle methods over the initial 60 min time period (Heng et al., 2008).

BSC Class II compounds are characterized by a higher degree of permeability than dissolution rate, making the dissolution rate the limiting factor in bioavailability. In order to more accurately depict the in vivo performance of such drugs, biphasic dissolution studies have been developed which provide an absorptive sink via a partitioning approach (McAllister 2010). In such studies, the dissolution media is composed of a bio-relevant aqueous phase as well as an organic phase such as octanol. The dissolution rate will therefore dictate the amount of drug available in solution for partitioning into the organic phase. Advantages of biphasic dissolution studies include prevention of accumulation of the drug in the aqueous phase which may lead to crashing out phenomena and no post sampling handling to eliminate undesired species as the partition process acts as a filter. In a study by Shi et al., a USP Apparatus II vessel was filled with 250 mL of 80 mM phosphate buffer (pH 6.8) and 200 mL of octanol. A standard USP II paddle was modified with a secondary paddle to allow agitation of both the aqueous and organic phases. The formulation to be tested was placed in an external flow through cell and the aqueous dissolution media was circulated through the cell by means of a piston pump and Teflon tubing (Fig. 2.9). Preoptimized parameters of 75 rpm paddle speed and 30-mL/min pump flow rate were used during testing as unpublished data demonstrated that they provide the strongest in vitro–in vivo correlations. Samples were taken from both the aqueous and organic phases at predetermined time points (Shi et al. 2010). A similar study has been performed in a USP Apparatus II dissolution vessel not incorporating the external flow through cell. Here, 500 mL of a sodium dihydrate phosphate-buffered aqueous phase and 100 mL of *n*-octanol were placed in a dissolution vessel held at 37°C and the formulation to be studied placed directly in the dissolution vessel. Uniquely, an automated pH titration and controlling device was placed in the vessel to apply a pH gradient over the duration of the test.

Fig. 2.9 Diagram of a biphasic dissolution test apparatus. From Shi et al. (2010). Reproduced with permission from the American Chemical Society

During analysis, the pH was initially held at two for 1 h mimicking gastric conditions. The media was then adjusted to pH 5.5 within 5 min to simulate gastric emptying into the upper intestine. At 5 h, the pH was adjusted to 6.8 where it remained for the duration of the study to simulate transit through the lower GI. Sampling was performed on both aqueous and organic phases at predetermined time points. The solubility of the compounds tested was significantly higher in acid than either basic media or *n*-octanol. Therefore, dissolution profile analysis reveals a significant amount of drug in solution while acidic conditions were held. However, following pH adjustment, the aqueous solubility dropped markedly. The presence of the organic phase allowed maintenance of sink conditions and prevented precipitation within the aqueous phase (Heigoldt et al., 2010).

2.4.2 *In Vivo* Testing

The above-outlined *in vitro* testing allows the researcher to select lead formulations based on their performance in dissolution testing. However, these studies are only indicative of performance, not absolute, as the physiological environment is far more complex than the conditions used in the laboratory. Although simulated intestinal fluids such as the model fasted duodenal fluid and simulated lung fluid mentioned above allow closer approximation to *in vivo* conditions, in order to truly understand the ability of a formulation to provide enhanced bioavailability of a poorly water-soluble compound animal models must be employed.

Unfortunately, there is no single surrogate animal species acceptable for all *in vivo* testing requiring selection of the appropriate model by the researcher.

Selection of the appropriate animal model will depend on numerous factors; however, in all cases, the smallest viable model should be used. Some factors influencing the choice of model should include the dose size, route of administration, required surgeries, the number of blood draws, and whether or not a crossover design is to be used. Rat models are often used for single- and multiple-oral-dose pharmacokinetic studies as multiple blood draws can be taken without significant risk of anemia. Rat models, however, are inappropriate for crossover studies as their growth rate is too rapid to allow for proper comparison of bioavailability between formulations. In such a case, a larger model such as a canine model may be required. Regardless of the model chosen, the protocol to be carried out must be approved by an institutional review board (IRB) and be in accordance with the Institutional Animal Care and Use Committee (IACUC; if applicable) or similar governing body at the location of the study. The following examples describe experimental protocols for both oral and inhalation studies of PWS drugs including information on dosing methods and sampling protocols, focusing on rodent models. Extraction methods for blood and tissue analysis will not be presented.

2.4.2.1 Administration Via Inhalation

The surface area of the distal airway is approximately 102 m^2 while the conducting airways is a mere $2\text{--}3\text{ m}^2$, allowing for much greater contact with the inspired gas or therapeutic aerosol (Patton 1996). Additionally, the thickness of the cell layer which makes up the respiratory region is progressively reduced from approximately $60\text{ }\mu\text{m}$ in the upper airway, to submicron thickness in the alveoli (Patton 2007). Similarly, the fluid layer at the cell surface decreases from $8\text{ }\mu\text{m}$ to approximately 70 nm in direct correlation with the decrease in cell thickness. These factors, coupled with the lack of digestive enzymes and bypass of first-pass metabolism, make pulmonary delivery an attractive route of delivery for PWS drugs.

In an effort to allow passive inhalation of a drug aerosol, a whole-body chamber was designed which allowed up to 14 mice to be dosed simultaneously. The solution or dispersion to be administered could be nebulized directly into the chamber exposing the unrestrained animals to the dose. Restraint during dosing may lead to physiological changes such as altered temperature regulation and can adversely affect an *in vivo* study. Therefore, elimination of the restraint may regulate rodent physiology, reducing variability in received dose. The whole-body apparatus was employed in the study of nebulized itraconazole nanoparticle dispersions. Using 10 mice, the formulation was first assessed for dose uniformity and it was shown that whole-body exposure yielded a variation of 13% relative standard deviation (Fig. 2.10). An *in vivo* study was then conducted to determine the lung concentration and residence time of the nebulized itraconazole. Three groups of 14 mice each were exposed to the aerosol generated by a 20 mg/mL dispersion for 20 min. Following dosing, two mice were sacrificed at time points of 0.5, 1, 2, 4, 6, 10, and 24 h, the lungs harvested, itraconazole extracted, and the concentrations normalized for weight (i.e., $\mu\text{g/g}$ lung tissue). As can be seen in Fig. 2.11, significant drug levels could be not only achieved

Fig. 2.10 Dose variability for mice exposed to nebulized itraconazole via whole-body dosing chamber (McConville et al. 2006)

Fig. 2.11 Itraconazole lung concentration versus time following whole-body exposure (McConville et al. 2006)

but also maintained following administration via inhalation (McConville et al. 2005; McConville et al. 2006). A similar study utilizing the same apparatus demonstrated enhanced bioavailability of itraconazole amorphous nanodispersions, with both lung and blood (cardiac puncture) samples being taken at each sacrifice time point (Yang et al. 2008).

While restraint-free whole-body dosing may provide the advantages of dosing many animals at once and minimizing stress to the animal, one must consider the

fact that these units provide whole-body exposure. As such, there is possible drug absorption through dermal and ocular routes as well as the oral route as the animals may consume drug deposited on their fur during grooming. This last fact may not be influential when looking strictly at lung deposition; however, it will be crucial for biodistribution studies as the oral dose may be selectively cleared by a specific organ (i.e., kidney/liver) (Phalen et al. 1984; Roy et al. 2003).

To limit whole-body exposure and prevent potential oral, dermal, and ocular exposure, nose-only dosing chambers have been developed for rodent models. These include commercial tower units in which rodents are attached perpendicular to the airflow. The generated aerosol flows vertically downward across the subjects' noses and the restrained animals passively breathe it in. A custom-built laboratory scale unit was used in a pharmacokinetic study of inhaled amorphous colloidal dispersions of itraconazole. Precatheterized (jugular vein) Sprague–Dawley rats were restrained using nose-only restraints (Battelle) and connected to a horizontal chamber such that only the nose of each rodent was inside the chamber. The dispersion was then nebulized with a circulating fan, providing a constant airflow of 1 L/min to propel the generated aerosol horizontally through the system and the attached rats were allowed to passively inhale the aerosol for 10 min. Animals were then returned to their cages and blood draws were taken through the jugular vein catheter at 0, 0.5, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 12, and 24 h post dosing. Collected samples were placed in preheparinized tubes to prevent clotting. Lungs were harvested from two rats immediately after each dosing to assess lung deposition, with all others being sacrificed and lungs harvested at 24 h (Yang et al. 2010). It should be noted that prior to any dosing, the animals must be acclimated to the restraints over a period of days to prevent any significant physiological changes during dosing resulting from stress.

While nose-only dosing chambers have proven effective for assessment of pulmonary formulations, deposition can occur in the upper airways as well as around the mouth. While this is likely to be only minor external deposition, there is still a risk of an oral dose as a result of grooming and potential poor deposition due to rodent activity within the restraining device. To avoid deposition in the upper airway or oral cavity a dry powder insufflator (DPI), such as that offered by Penn-Century (Fig. 2.12) can be used to administer a dry powder formulation directly to the lungs of an animal. Using an attached syringe to generate airflow, the powder under study can be expelled intra-tracheally for deep lung deposition. Such a device was used on anesthetized rats (via diethyl ether) to deliver 5 mg of PLGA nanocomposite particles loaded with TAS-103, a PWS antitumor agent. Following dosing, blood was collected at 0.5, 1, 2, 4, and 8 h through the retro orbital plexus region. Withdrawn blood was then centrifuged at low temperature (5°C) for 10 min and a sample of the supernatant collected for subsequent plasma concentration analysis. Lung tissue was also harvested for deposition analysis (Tomoda et al. 2009). Another study examined pulmonary delivery utilizing the same device. Using a dose of 10 mg/kg, scutellarin was loaded into the tip of the DPI, attached to a syringe and inserted into the trachea of the anesthetized rat. Depression of the syringe plunger produced the aerosol for delivery directly to the lungs. This pulmonary powder formulation was compared directly to intratracheal administration of a solution using a Penn-Century

Fig. 2.12 Penn-Century Model DP-4 M dry powder insufflator with attached syringe

Model IA-1B with a volume of 1 mL/kg. In both cases, the animals were held in the upright position for 1 min following removal of the delivery device to ensure deposition (Liu et al. 2008). It should be noted that the dose administered in the above studies is much greater than a dose receivable by a murine model. To accommodate for the necessary reduction in dose, 200–300 μg of powder was loaded into polyethylene tubing (1 cm in length) by dipping the tubing directly in the dry powder. This loaded tube was then inserted in the hole leading from the insufflator chamber to the cannula and a syringe was attached. Two hundred and fifty microliters of air was used to during dosing to disperse the powder. If necessary, additional puffs of air at identical 250- μL increments were used to disperse the material from the device (Morello et al. 2009). Additional studies using DPIs have proven successful in additional animal models including guinea pigs (Sung et al. 2009) and Beagle dogs (Surendrakumar et al. 2003).

2.4.2.2 Oral Administration

The oral route of administration is highly desired for an end formulation due to high patient compliance and ease of administration. However, the gastrointestinal tract presents numerous obstacles preventing successful oral delivery, including environments of varied pH, reactive enzymes, and biological clearance systems. These factors combined with limited aqueous solubility make oral delivery of PWS drugs especially challenging (O'Donnell and Williams 2011). As discussed above, many formulators are attempting to generate systems capable of supersaturating the GI

milieu in an effort to overcome bioavailability issues associated with poor aqueous solubility. While these systems may prove promising during *in vitro* supersaturation studies, success upon *in vivo* application must be determined via animal modeling.

As PWS drugs are often not formulated as solutions, administration to the animal model via the oral route relies upon the dosing of powder formulations. This can be accomplished using a size 9 capsule and corresponding dosing syringe such as those offered by Torpac and Capsugel. Assuming a powder density of 1 g/cc, these capsules hold up to 25 mg of powder and dissolve within the rodent's stomach within 10 min. These capsules have been utilized for low-density amorphous solid dispersions of tacrolimus prepared by ultra-rapid freezing. A nominal dose of 5 mg/kg was dosed to male Sprague–Dawley rats (300 g rats; approximately 1.5 mgs/capsule) using the size 9 gelatin capsules from Torpac. In order to ensure adequate GI media was present for dissolution of the capsule and that no esophageal sticking had occurred, 0.4 mL of water was immediately given via oral gavage following capsule administration. As these rats were precatheterized, blood draws could easily be taken at 0.5, 1, 1.5, 2, 3, 4, 6, and 24 h post dose. At each sampling time point, the withdrawn blood was replaced with heparinized normal saline (6 units/ μL) (Overhoff et al. 2008). In a study of the PWS drug letrozole, a rat model was selected utilizing both male and female rats. The drug was then administered in one of three ways: oral gavage, orally via a Torpac size 9 capsule, or IV infusion via the ophthalmic venous plexus. For capsule administration, an amount of formulation equivalent to 1.0 mg API was placed in the capsule and administered orally. Similar to the previously discussed study, a bolus of water (500 μL) was provided following administration of the capsule. Oral gavage was performed by generating a suspension of the native compound in a 12.5% aqueous ethanol media. Sonication provided adequate dispersion of the material immediately prior to dosing. The test formulations for oral gavage were made into solutions using the same 12.5% aqueous ethanol media. IV dose solutions were prepared into 1 mg/mL solutions, filtered through a 0.45 μm filter, and immediately dosed. In order to generate a comparable IV dose of the native compound, the API was first dissolved in DMSO, and a 300- μL aliquot of this stock solution was diluted to 10 mL using saline to yield a 0.297 mg/mL solution. This was then filtered and dosed. Contrary to the precatheterized rodents from the previous study, tail vein collection of blood samples was performed using mini-capillary blood collection tubes pretreated with EDTA di-potassium salt. Samples were stored at -80°C until analysis (Wempe et al. 2007). Figure 2.13 depicts the pharmacokinetic profiles of the IV versus capsule-administered API in the presence and absence of HBen β CD. As can be seen, a drastic difference in bioavailability was observed for male versus female rats depicting the importance of not only proper species selection but also gender selection thereof.

For PWS drugs in which a solution cannot be prepared for oral gavage and a capsule is not capable of holding a sufficient dose, a suspension or dispersion can be prepared as was done with the native letrozole. As previously mentioned, the bioavailability of itraconazole is significantly hindered by its poor aqueous solubility, especially upon pH transition to neutral media. Therefore, supersaturating the neutral media of the GI following stomach emptying may enhance bioavailability.

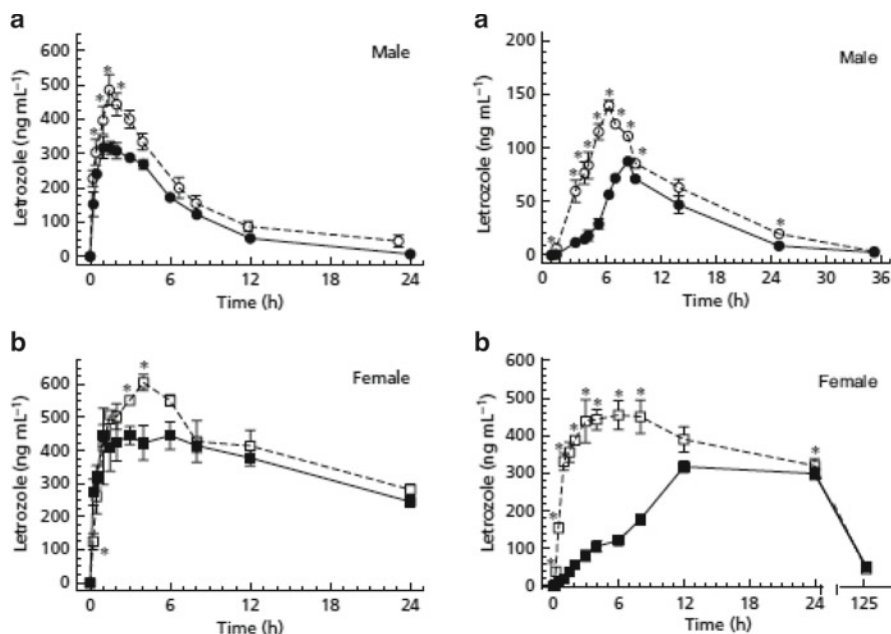

Fig. 2.13 Pharmacokinetics of IV (left) and capsule administered letrozole. *Closed symbols*: API in absence of HBE β CD; *Open symbols*: API in presence of HBE β CD. Reproduced with permission from John Wiley and Sons

Formulations of itraconazole with polymeric stabilizers were prepared by HME and dosed to male Sprague–Dawley rats at a nominal dose of 30 mg/kg. Dosing was performed by preparing an aqueous dispersion of the formulations immediately prior to dosing such that a 400- μ L aliquot contained 9 mg API. This dispersion was then provided via oral gavage and blood draws taken through a jugular vein catheter. Indeed, these formulations provided a threefold increase in itraconazole absorption (Miller et al. 2008). In a similar study, engineered particles of itraconazole were dispersed in deionized water at a concentration of 4 mg/mL and dosed by oral gavage. Unique to this study is the comparison of the engineered material to the marketed multiparticulate capsule formulation, Sporonox. As the marketed capsules are far too large to be dosed to a rodent, ten capsules were opened and the potency per pellet determined. An appropriate number of pellets to reach a dose of 15 mg/kg were then placed in a size 9 capsule and dosed with the corresponding syringe. Indeed, the novel particle formulation outperformed the marketed product providing a significant improvement in bioavailability (Fig. 2.14) (DiNunzio et al. 2008). If a method is to be used in which the drug is dispersed in a liquid carrier, it is important to understand the maximum volume that can be dosed to the selected species without interrupting GI function. For example, doses should be kept below 4 mL/kg in rat models to prevent spontaneous release through the pyloric sphincter (Alban et al. 2001).

Fig. 2.14 In vivo plasma profile of itraconazole dosed to rats via oral gavage of dispersion (*square*) and adapted marketed formulation in size 9 capsules (*diamond*). $N=6$. Reproduced with permission from American Chemical Society

2.5 Conclusions

In order to optimize the formulation of a poorly water-soluble drug it is imperative to gain an understanding of the physical and chemical nature of the compound. This can be accomplished through preformulation studies, including solubility screenings, solid-state characterization, dissolution testing, and in vivo studies. Proper application of these methods as described above will aid the formulation scientist in directing the development of a poorly water-soluble compound in the most promising direction.

Method Capsule 1

pH-Solubility Profile by Direct Determination in Aqueous Suspension

Based on the method reported by Li et al. (2005)

Objective

- To determine the pH-solubility profile of haloperidol and the corresponding hydrochloride and mesylate salts.

Equipment and Reagents

- Haloperidol free base
- Haloperidol hydrochloride
- Haloperidol mesylate
- Deionized water

- Hydrochloric acid solution
- Sodium hydroxide solution
- 10 mL sealable vials
- Water bath or environmental shaker capable of maintaining 37°C
- 0.45 μm acrodisc filters w/attached syringe
- UV spectrophotometer (250 nm detection wavelength)

Method

- Add 5 mL of water to each 10 mL vial, 9 total, 3 for each compound.
- Place excess solids (one compound per vial) in the prefilled vials such that a suspension results.
- Titrated each vial to pH 1 via HCl and NaOH solution addition.
- Equilibrate the vials at 37°C for 24 h. Note: agitation recommended during equilibration if possible.
- Following equilibration, verify that no pH shift has occurred.
- Remove an aliquot of the suspension and filter through a 0.45 μm (or smaller) filter.
- Dilute sample with suitable organic solvent (i.e., acetonitrile) to obtain concentrations in the working linear range of the spectrophotometer.
- Analyze samples on UV spectrophotometer at 250 nm.
- Titrate each vial with NaOH and HCl solutions to pH 2.
- Equilibrate vials for 24 h under identical conditions.
- Confirm no pH shift upon equilibration.
- Repeat sampling and analysis procedure as above.
- Continue titration, equilibration, sampling procedure through pH range of 1–13, or desired regions thereof.

Results

- Plotting the solubility ($\mu\text{g/mL}$) versus pH of the free base and its HCl salt revealed a significant drop in solubility of both compounds above pH 5. Additionally, the plot demonstrates no significant difference in the aqueous solubility between the free base and HCl salt through pH 7.
- The pH versus solubility plot for the mesylate salt of haloperidol revealed significantly higher solubilities of the API through pH 5. Similar to the free base and HCl salt, solubility of the API decreased significantly above pH 5.

Method Capsule 2

Analysis of Drug–Excipient Interactions Via Differential Scanning Calorimetry

Based on the method reported by Mura et al. (1998a) *Thermochimica Acta*.

Objective

- To determine compatibility of picotamide in the presence of excipients commonly used in tableting formulations.

Equipment and Reagents

- Picotamide recrystallized from water–ethanol 8:1.
- Excipients: PVP K30, PVPXL, tartaric acid, ascorbic acid, hydroxypropylmethyl cellulose, hydroxyethyl cellulose, sodium carboxymethyl cellulose, microcrystalline cellulose, Veegum F, Arabic gum, cornstarch.
- Mortar pestle
- Microbalance (mg scale)
- Differential scanning calorimeter
- Aluminum pans with perforated lids

Method

- Sieve each material and obtain the 75–150 μm fraction for analysis.
- Prepare individual physical mixtures the API and each excipient (1:1) in a mortar using a spatula to gently blend the components.
- Prepare co-ground mixtures of each drug:excipient combination by grinding an aliquot of the corresponding physical mixture in a mortar with a pestle for 10 min.
- Prepare kneaded mixtures of each drug:excipient combination by slurring an aliquot of the corresponding physical mixture with ethanol (1–2 mL) and grinding in a mortar with pestle to obtain a paste. Dry under vacuum in a desiccator at room temperature to a constant weight.
- Place aliquots of physical mixtures at 60°C for drug–excipient storage stability analysis.
- Analyze each individual component, physical mixture, co-ground mixture, kneaded mixture, and stability sample in the following manner: Place an aluminum pan (without lid) on the microbalance and zero the scale. Fill the pan with approximately 5–10 mg of the material for analysis. Place the filled pan back on the balance and record the exact weight of filling. Place a lid in the filled pan. Place the pan in the DSC apparatus on the sample side. A reference pan with lid should be placed on the reference cell. Perform scan at 10 K/min from 30–200°C.

Results

- Picotamide monohydrate exhibits an endothermic event at $123.0 \pm 2.4^\circ\text{C}$.
- Maintenance of the anhydrous state for physical mixtures and co-ground mixtures with microcrystalline cellulose, cornstarch, methocel, and ethocel indicate compatibility.
- Hydration of the API in physical mixtures with Veegum and Arabic gum indicates incompatibility.
- Fresh and stored physical blends with PVP exhibited no interactions. The presence of the dehydration peak at 124°C for ground mixtures with PVP-XL indicates incompatibility. The absence of the picotamide melting endotherm for co-ground mixtures with PVP-K30 indicates amorphization of the API and dissolution into the polymeric carrier.
- The presence of acidic excipients yielded broadening and downshift of thermal effects followed by exothermic decomposition for all samples indicating strong incompatibility.

Method Capsule 3

X-Ray Diffraction Parameter Optimization

Based on the method reported by Tiwari et al. (2007)

Objective

- To optimize the scan parameters for X-ray diffraction analysis including step size and dwell time as well as to assess the influence of particle size.

Equipment and Reagents

- Olanzapine polymorphs I and II
- X-ray diffractometer
- Poly methyl methacrylate sample holder or equivalent
- Glass microscope slide or similar

Method

- Pass polymorph I through multiple sieves (i.e., BSS #80, 120, and 240) collecting aliquots of each sieve fraction.
- Optimization of scan rate—scan a 5% w/w mixture of polymorph I in polymorph II over the range of 3–40° 2 Θ under the following conditions and identify the parameters capable of providing the greatest number of identified peaks in the least amount of time:
 - Step time of 0.5 s, step size of 0.025°
 - Step time of 0.5 s, step size of 0.0125°
 - Step time of 1 s, step size of 0.0125°
 - Step time of 5 s, step size of 0.05°
 - Step time of 5 s, step size of 0.0125°
- Using the selected optimized scan rate, analyze the aliquots of each sieve fraction to assess the influence of particle size.

Results

- A step time of 5 s and step sizes of 0.05 and 0.0125° allowed identification of four distinct peaks.
- Lower step times of 1 s and 0.5 s allowed identification of only two and one peaks, respectively, regardless of step size.
- The step size of 0.05° was selected as it drastically reduced the scan time from 246.66 min to 61.66 min.
- Particle size significantly influenced the number of identifiable peaks.
- Sieve fraction BSS #120/240 significantly improved resolution compared to larger particle-size fractions.

Method Capsule 4

Accelerated Stability Monitoring of Amorphous Solid Dispersions

Based on the method reported by DiNunzio et al. (2010a, b, c)

Objective

- To assess formulation stability against recrystallization upon storage for amorphous itraconazole compositions produced by hot-melt extrusion and Kinetisol dispersing.

Equipment and Reagents

- High-density polyethylene (HDPE) bottles or similar with induction sealing capability.
- Oven capable of maintaining $40^{\circ}\text{C} \pm 1^{\circ}\text{C}$.
- Saturated salt solution capable of maintaining 75% relative humidity within 40°C oven.
- X-ray diffractometer (XRD)
- Sample holder for XRD

Method

- Analyze bulk itraconazole and excipients individually by XRD over the scan range of $5\text{--}50^{\circ} 2\Theta$ with a step size of 0.05° and a dwell time of 3 s. Identify major characteristic peaks to be used in subsequent analysis.
- Analyze physical mixtures of drug and excipients at ratios identical to those used for the final formulation by XRD employing the same parameters as above. Identify the major characteristic peaks of itraconazole present in physical mixtures.
- Following formulation production, immediately obtain XRD profiles for each product using identical scan parameters as before. Identify major characteristic peaks of itraconazole and corresponding intensities if present.
- Place 2 g of a single formulation into a 30-mL HDPE bottle.
- Prepare three bottles for each formulation for each of the three time points.
- Induction seal each bottle.
- Verify induction seal robustness prior to placing on stability.
- Place all samples in 40°C 75% RH oven.
- At 1 month remove three samples of each formulation for analysis.
- Allow samples to equilibrate to room temperature for 24 h.
- Open containers and analyze powders individually by XRD using identical parameters as described above for characteristic crystalline peaks of itraconazole.
- Repeat sample removal, equilibration, and analysis at 3 and 6 months.
- Generate a plot for the XRD data of intensity versus angle (degrees 2Θ) for all formulations at a single time point for comparison. Do this for each time point.

Results

- Analysis of bulk itraconazole revealed numerous characteristic crystalline peaks between 10 and 35° 2 θ .
- XRD diffraction patterns of formulations immediately post production exhibit amorphous halos and lack any characteristic itraconazole peaks.
- Materials produced by kinetisol dispersing which contained no plasticizer exhibited no peak growth over time when stored at accelerated conditions.
- Formulations produced by hot-melt extrusion exhibited gradual growth of characteristic itraconazole peaks, indicating recrystallization upon storage.

Method Capsule 5**BET Specific Surface Area Determination for a High Surface-Area Heat-Liable Material**

Based on the method reported by Engstrom et al. (2007)

Objective

- To determine the specific surface area of protein powders produced by spray freezing into liquid.

Equipment and Reagents

- Protein powder produced by spray freezing into liquid.
- Quantachrome Nova 2000 BET apparatus including sample cells.
- Dry box
- Liquid nitrogen
- Nitrogen gas: high purity, dry
- Analytical balance

Method

- Using the analytical balance, weigh the empty sample cells and record the weights.
- Within the dry box, add powder sample to the BET sample cells. As the device has two cells which can be analyzed simultaneously, all powders for analysis are to be analyzed in duplicate.
- Using the analytical balance record the weight of the full sample cell.
- Attach filled sample cells to degassing station ports.
- Engage vacuum
- Allow samples to degas under vacuum for 12 h.
- Fill liquid nitrogen Dewar with liquid nitrogen to the maximum fill level.
- Repressurize the system, remove sample cells, and, using the analytical balance, immediately record the weights of the degassed samples. Calculate sample weight as: Degassed sample cell weight–empty sample cell weight.

- Attach sample cells to analysis ports of the BET apparatus. Verify the level of liquid nitrogen in the Dewar is sufficient for analysis.
- Using nitrogen as the adsorptive gas analyze the powder samples over the relative pressure range of 0.05–0.30 and use the BET equation to fit the adsorption data.

Results

- Surface areas of powders produced by spray freezing into liquid ranged from 13 to 134 m²/g.
- Increasing the feed concentration decreased the specific surface area of the powders.
- Increasing the feed concentration decreased the submicron particle content.
- Increasing the droplet size during spray freeze drying resulted in lower specific surface areas.

Method Capsule 6 Supersaturation Dissolution Studies Using the Syringe/Filter and Microcentrifuge Methods

Based on the method reported by Curatolo et al. [2009](#)

Objective

- To determine the ability of HPMCAS in initiation and maintenance of supersaturation of an experimental compound.

Equipment and Reagents

- Experimental compound CMPD 2
- HPMCAS-MF
- 10-mL syringes
- Model fasted duodenal fluid preheated to 37°C.
- Oven capable of maintaining 37°C.
- Wheel capable of rotating syringe in horizontal position at 50 rpm.
- 20-gauge hypodermic needles
- 13 mm, 0.45 µm polyvinylidene difluoride syringe filters.
- Test tubes
- Polypropylene microcentrifuge tubes
- Microcentrifuge
- Vortex mixer
- Small volume pipette (i.e., 10–100 µL)
- Diluting solution: 60:40 1.7 wt.% ammonium ascorbate:acetonitrile.
- HPLC: Phenomenex ultracarb ODS 20 analytical column, PDA detection at 215 nm.

Method

- Syringe/Filter method:
- Accurately weigh 7.5 mg of 67% CMPD 2:HPMCAS-MF formulation and add to an empty 10 mL syringe with attached 20-gage needle.
- Draw 10 mL of model fasted duodenal fluid preheated to 37°C into the syringe via the attached needle.
- Replace attached needle with 13 mm syringe filter.
- Shake syringe vigorously for 30 s.
- Expel six drops of the solution as waste. Collect drops 7–19 as a sample.
- Draw syringe plunger back to generate an air bubble.
- Place syringe on rotating wheel (50 rpm) in the 37°C oven.
- Dilute sample 1:1 with diluting solvent.
- Repeat sampling procedure at $t=5, 10, 20, 40, 90, 180$ min.
- Analyze samples on HPLC to quantify CMPD 2.
- Microcentrifuge method
- In a 37°C controlled-temperature box, weigh 1.8 mg of formulation into a microcentrifuge tube.
- Add 1.8 mL of model fasted duodenal fluid to the tube.
- Close tube, start timer, and vortex mix for 60 s.
- Transfer tube to microcentrifuge, allow to stand for 6 min, then centrifuge at 13,000 g for 60 s.
- At the 10 min mark on the timer, remove a 25- μ L sample from the supernatant via a pipette. Immediately dilute 1:1 with diluting solution.
- Resuspend the material via vortex mixing for 30 s.
- Place tube back in centrifuge. Allow tube to stand undisturbed until the next sampling time point.
- At each sampling time point, centrifuge the tube for 60 s, remove supernatant sample and resuspend as described. Dilute sample 1:1 with diluting solution.
- Analyze all samples via HPLC to quantify CMPD 2.
- Plot the dissolved drug concentration versus time dissolution profile for the API.

Results

- Compound 2 has an aqueous solubility of 1 μ g/mL.
- The 67% compound 2 solid dispersion formulation with HPMCAS resulted in supersaturation of the test medium.
- Maximum concentrations of approximately 130 μ g/mL were achieved.
- HPMCAS-MF initiated and maintained supersaturation of compound 2 to a greater extent than HPC, PVAP or the crystalline bulk drug.
- Both methods proved successful in achieving supersaturation

Method Capsule 7

Biphasic Dissolution Testing Utilizing an External Flow through Cell

Based on the method reported by Shi et al. (2010)

Objective

- To examine the dissolution profiles of three celecoxib formulations using a biphasic dissolution-testing method incorporating an organic phase for drug partitioning.

Equipment and Reagents

- Octanol
- Sodium phosphate monobasic monohydrate
- Sodium hydroxide
- Gelatin capsules
- Commercial Celebrex capsules (200 mg dose strength).
- Extracted celecoxib (extracted from Celebrex capsules via ethanol and subsequent evaporation method).
- USP Dissolution Apparatus II
- USP IV flow through cell
- Piston pump
- Teflon tubing
- Modified apparatus II paddle incorporating a second paddle capable of agitating the organic layer during dissolution testing.
- HPLC (mobile phase 55:45 v/v acetonitrile:ammonium acetate solution).

Method

- Place 250 mL of 80 mM phosphate buffer (pH 6.8) in the dissolution vessel.
- Add 200 mL of octanol to the dissolution vessel.
- Prior to beginning the study, saturate the aqueous phase with octanol and vice versa by agitating the mixture for 30 min.
- Allow all media to equilibrate to $37^{\circ}\text{C} \pm 0.2^{\circ}\text{C}$.
- Place the Teflon tubing (inlet and outlet) such that the ends are well within the aqueous phase of the dissolution media.
- Set the paddle speed to 75 rpm.
- Place the formulation for analysis into the flow through cell.
- Set the pump flow rate to 30 mL/min.
- At time points of 15, 30, 45, 60, 75, 90, and 120 min remove a 1-mL sample from the aqueous phase and a 100- μL sample from the organic phase. Do not replace the media.
- Immediately centrifuge the aqueous phase samples at 14,000 rpm for 6 min. Collect the supernatant for HPLC analysis.
- Immediately dilute the organic phase samples 100-fold with HPLC mobile phase.
- Quantitative celecoxib via HPLC analysis; adjustment for dilution mathematically.

Results

- Corresponding single-phase studies (aqueous; USP Apparatus II) under sink conditions were not discriminatory for formulation performance.
- Nonsink two-phase dissolution revealed the same formulation performance rank order in the aqueous phase.
- Analysis of the octanol phase reveals the self-emulsifying drug delivery system (SEDDS) outperformed the solution and capsule formulations.
- SEDDS provided a higher amount of free drug compared to the solution formulation in which the drug was associated as surfactant micelles.
- SEDDS formulation supersaturated the aqueous media under nonsink-biphasic dissolution conditions, allowing greater partitioning into the octanol phase.
- Aqueous phase AUC values from both single and biphasic dissolution testing exhibited no correlation with in vivo AUC values.
- Analysis of the octanol phase from biphasic studies revealed a rank-order correlation to in vivo results.

Method Capsule 8
Supersaturation Dissolution Testing of Amorphous Compositions of a Poorly Water-Soluble Drug

Based on the method reported by DiNunzio et al. [2008](#)

Objective

- To assess the supersaturation extent and duration of amorphous compositions of itraconazole using concentration enhancing polymers.

Equipment and Reagents

- Itraconazole; bulk drug and formulations prepared via thin film freezing.
- Commercial itraconazole capsules (Sporanox).
- Size 9 porcine gelatin capsules.
- USP Dissolution Apparatus II with autosampler.
- 0.1N hydrochloric acid.
- 0.2M Na₃PO₄ solution.
- 0.2 μm PTFE membrane, 13 mm Acrodisc syringe filters.
- 5 mL syringes
- HPLC System (5 μm^cC18(2) 100 Å, 150 mm×4.6 mm column, flow rate of 1 mL/min, detection at 263 nm).
- HPLC mobile phase (70:30:0.05 acetonitrile:water:diethanolamine).
- HPLC vials.
- Vortex mixer

Method

- Preheat 735 mL of 0.1N HCl in each dissolution vessel to 37°C.
- Accurately weigh an amount of formulation equivalent to 37.5 mg of itraconazole. This corresponds to approximately 10× the equilibrium solubility in 0.1N HCl.

- Pre-wet the weighed powder with 15 mL of heated 0.1N HCl (37°C).
- Add the prewetted powder slurry to the dissolution vessel.
- After 2 h, add 250 mL of 0.2 M Na₃PO₄ to each vessel to bring the pH to 6.8.
- At time points of 60, 120, 130, 150, 180, 240, 300, 360, and 1,440 min, a 5 mL sample is to be taken via the autosampler without replacement of the withdrawn media.
- Immediately filter samples following withdraw through a 0.2- μ m PTFE membrane.
- Immediately dilute filtrate 1:1 with mobile phase and vortex mix. Transfer to an HPLC vial.
- Analyze all samples by HPLC to quantify itraconazole adjusting for the volume change and dilution mathematically.

Results

- Sporanox pellets were able to rapidly and extensively supersaturate the acidic media. Following the pH transition, the drug rapidly precipitated.
- Thin film freezing formulations resulted in significantly reduced acidic media concentrations as the polymers used were enteric.
- Following pH change, cellulose acetate phthalate and polyvinyl acetate phthalate formulations showed the greatest supersaturation in neutral media.
- Higher ratios of itraconazole:polymer yielded lower degrees of supersaturation.
- Cellulose acetate phthalate formulations provided longer half-life values for drug in solution, indicating strong concentration enhancing properties.

Method Capsule 9 Pulmonary Delivery to the Murine Model Via Dry Powder Insufflation

Based on the method reported by Morello et al. (2009)

Objective

- To achieve successful pulmonary administration of the tuberculosis vaccine (BCG) to the murine model by dry powder insufflation.

Equipment and Reagents

- Female BALB/c mice (6–12 weeks old, 18–24 g).
- BCG vaccine spray-dried powder.
- Polyethylene tubing (1.19 mm diameter) cut into lengths of approximately 1 cm.
- Microbalance
- Penn-Century dry powder insufflator model DP-4 M.
- Penn-Century model AP-1 air pump.

- Rodent work stand
- Lidocaine applicator
- Mouse-sized speculum
- Plastic incisor loop
- Otoscope set
- Ketamine HCl, xylazine, and acepromazine
- Yohimbine solution (0.04 mg/mL)
- Syringe and 21-gauge needle
- Cage maintained at 37°C.

Method

- Prepare mixture of ketamine/xylazine/acepromazine by mixing 2 mL ketamine at 100 mg/mL, 0.4 mL of xylazine at 100 mg/mL and 0.6 mL of acepromazine at 10 mg/mL with 7 mL of sterile phosphate-buffered saline.
- Anesthetize the mouse via an intraperitoneal (i.p.) injection (100 μ L/20 g body weight) of ketamine/xylazine/acepromazine mixture
- Load 200–300 μ g of powder into the 1 cm segment of polyethylene tubing by dipping the end vertically into the powder bed 4–6 times.
- Place the filled polyethylene tube into the hole within the insufflator chamber.
- Attach base of insufflator to the cannula.
- Place the mouse in the supine position on the mouse work station and place the incisor loop and lateral supports in position.
- Raise the stand to 60°.
- Using the otoscope, obtain a clear view of the trachea.
- Using the speculum to guide the applicator, apply lidocaine to the arytenoid cartilage.
- Re-obtain visual focus of the trachea with the otoscope.
- Insert the cannula of the insufflator device into the tracheal opening.
- Remove the otoscope and attach the air pump.
- Depress plunger on air pump 4–5 times. Monitor rise and fall the upper chest as confirmation of proper insufflation.
- Remove mouse from the work stand and give an i.p. injection of 0.11 mg/kg yohimbine solution (0.04 mg/mL)
- Provide 300 μ L 0.9% saline subcutaneously to aid recovery.
- Move mouse to a 37°C cage until awake.

Results

- Application of this method allowed rapid administration of the compound relative to similar methods.
- $\geq 90\%$ of loaded powder was delivered to the lungs.
- 91% of the loaded dose reached the lungs.
- Minor pulmonary damage occurred as a result of the procedure; however, mice were asymptomatic and congestion/hemorrhage resolved over time.
- The method developed can be modified for use with larger animals by adjusting the dose and air volumes employed.

Method Capsule 10

Oral Drug Delivery of a Poorly Water-Soluble Drug to the Rat Model

Based on the method reported by Wempe et al. [2007](#)

Objective

- To determine the bioavailability of letrozole complexed with hydroxybutenyl- β -cyclodextrin (HBen β CD) compared to that of the native API via an oral dose administered as a suspension or solution to the rat model.

Equipment and Reagents

- Letrozole, complexed to HBen β CD and unprocessed.
- Male and female Sprague–Dawley rats (260–294 and 218–262 g, respectively).
- 1-mL syringe with 0.01-mL graduations.
- Sterile glass vials
- Ethanol
- Sterile water
- Sonicator
- Oral gavage needle (16 gage).
- Mini-capillary tubes containing EDTA di-potassium salt.

Method

- Weigh 5.2 mg of letrozole (uncomplexed) into a sterile glass vial.
- Immediately before dosing, dilute with 12.5% ethanol in water to a concentration of 1 mg/mL using sonication to disperse.
- Weigh 626.2 mg complexed letrozole-HBen β CD into a glass vial.
- Immediately before dosing, dilute with 12.5% ethanol in water to generate a 1 mg/mL solution.
- With the gavage needle attached to the syringe, draw in the desired dose of the suspension or solution to be administered.
- Holding the rat vertically while supporting the hind legs against the body, insert the gavage needle extending it into the stomach and expel the dose. Immediately remove the gavage needle from the animal.
- Repeat dosing for all rats.
- At time points of 0.45, 1.5, 2, 2.6, 2.9, 3.6, 5.1, 6.2, 8.3, 13.9, 24.8, and 36.3 h, collect 125 μ L blood samples through the tail vein directly into mini-capillary tubes containing EDTA di-potassium salt.
- Immediately following blood sample collection, cap the tube and place on dry ice. Keep samples frozen at -80°C until sample preparation for analysis.

Results

- Letrozole was eliminated from the blood of male rats within 36 h following dosing via oral gavage.
- The pharmacokinetics of letrozole are strongly gender-dependent.

- Dosing of letrozole-HBen β CD yielded a twofold increase in the AUC compared to a suspension of the uncomplexed drug.
- Oral dosing of the complexed formulation increased the C_{\max} from 87 to 140 ng/mL.
- The T_{\max} was decreased from 8.4 h to 6.3 h by the HBen β CD formulation.
- Solubility limits the rate and extent of absorption in male rats while only limiting the rate of absorption in female rats.
- Complexation of letrozole with HBen β CD improved oral absorption in male rats while maximizing absorption in female rats

Chapter 3

Solid-State Techniques for Improving Solubility

Justin R. Hughey and Robert O. Williams III

Abstract Poor aqueous solubility of a drug substance can often be attributed to strong intermolecular forces within its crystal lattice which, in turn, prevent molecules from escaping in solution. Through the use of solid-state chemistry, it is possible to modify the crystal structure in such a way that mitigates intermolecular forces, thus improving aqueous solubility and increasing rates of dissolution. Solid-state techniques utilized for solubility enhancement include the formation of salts, polymorphic or amorphous forms, and co-crystals. Each technique has specific advantages and, in some cases, disadvantages that may prevent its successful use. The purpose of this chapter is to describe each of the methods, allowing the reader to gain an understanding of solid-state modifications available for solubility enhancement.

3.1 Introduction

The number of newly developed chemical entities exhibiting poor water solubility has increased dramatically in recent years (Lipinski et al. 2001; Lipinski 2002). In many cases, this intrinsic property results in poor or erratic dissolution in biological fluids and, consequently, poor bioavailability. Improving aqueous solubility of these compounds, even temporarily, can have a significant impact on in vivo performance.

Aqueous solubility of a drug substance is primarily a function of its lipophilicity and intermolecular forces within the crystal lattice (Jain and Yalkowsky 2001; Jain et al. 2006). Therefore, solubility enhancement techniques typically focus on

1 University Station A1920, Austin, TX 78712, USA
e-mail: justinhughey@utexas.edu

addressing these two properties independently. In the case of high lipophilicity, techniques such as solubilization in co-solvents, micelle formation, and complexation are often employed (Loftsson and Brewster 1996; Dannenfelser et al. 2004; Torchilin 2007). Similarly, when poor aqueous solubility is due to strong intermolecular forces within the crystal lattice, solid-state modification can be utilized. Solid-state modification can be classified as methods that modify supramolecular arrays of the same components by means of forming polymorphs or amorphous solids and methods that change molecular components of the crystal network by means of salt, co-crystal, or solvate formation (Rodríguez-Spong et al. 2004).

This chapter discusses the concepts and applications of solid-state technologies to improve the aqueous solubility, dissolution rates, and thus bioavailability of poorly water-soluble drug substances. Specifically, these methods include salt formation, polymorphs, amorphous solids, and co-crystals.

3.2 Pharmaceutical Salts

When an acid and base are combined, the anion of the acid and the cation of the base react to form a salt. Therefore, a drug substance classified as a weak acid or a weak base may be combined with a suitable base or acid, respectively, to form a pharmaceutical salt (Corrigan 2006). In doing so, physicochemical properties of the drug substance, such as solubility, hygroscopicity, stability, and processability, are manipulated and, in many cases, optimized (Berge et al. 1977). Oftentimes, the primary goal of pharmaceutical salt formation is to increase aqueous solubility and thus bioavailability of the drug substance (Gould 1986). The ability to circumvent undesirable characteristics of the parent drug such as poor aqueous solubility without adversely affecting its pharmacological activity makes the technique particularly appealing. Interest in the formation of pharmaceutical salts has increased significantly over the last 60 years and the technique has become relatively common (Serajuddin 2007).

The decision to utilize pharmaceutical salts is one that should be made at the very early stages of pharmaceutical drug development. Historically, salts were often chosen based on their ease of preparation and raw material costs without taking into consideration important physicochemical properties such as physical and chemical stability, hygroscopicity, and pH-dependent dissolution rates (Serajuddin 2007). Salts of a single drug substance, prepared from different counterions, may behave quite differently due to variable physical, chemical, and thermodynamic properties (Pudipeddi and Serajuddin 2005). Substitution of a more suitable salt for a sub-optimal salt in the drug development process is costly in terms of time and resources as many of the biological, toxicological, formulation, and stability tests would need to be repeated. Recently, Gross et al. reported that the selected salt form of a developmental compound (NBI-75043) was a solvate, hygroscopic, and exhibited a low melting point (Gross et al. 2007). The researchers were able to develop a more suitable salt through a relatively simple screening process. Therefore, it is critical to be

Fig. 3.1 Overall distribution of anions used to form salts of weak bases in the Orange Book. From Paulekuhn et al. (2007)

as thorough as possible at the early stages of development such that the optimal salt is initially chosen.

In terms of salt formation, one of the most important parameters of the drug substance is the pK_a values of ionizable groups (Bastin et al. 2000). Once these values are known, potential salt-forming agents can be selected based on known pK_a values of salt-forming agents, or counterions (Gould 1986). In order to ensure sufficient proton transfer from the acidic to the basic species, the difference in pK_a values between an ionizable group and that of the counterion should be greater than 3 units (Bowker and Stahl 2008). However, a difference of 2 units has been reported in the literature as being acceptable (Wells 1988; Tong and Whitesell 1998; Black et al. 2007).

Overall distributions of anions utilized to form pharmaceutical salts are illustrated in Fig. 3.1. It is clear that chloride is the most common anion utilized to form salts of weakly basic drugs. This is primarily due to the low pK_a value of hydrochloric acid and its ability to readily form salts with weak bases. However, loss of volatile hydrochloric acid is a stability concern with very weak bases (Lee and Hoff 2002). Other strong acid counterions such as mesylate and sulfate readily form salts due to low pK_a values, with mesylate salt forms becoming increasingly common (Elder et al. 2010). The overall distribution of cations utilized for forming salts with weak acids is shown in Fig. 3.2. Sodium is by far the most commonly used cation. However, sodium salts often have a tendency to form hydrates and exhibit hygroscopicity so control of water content during their synthesis is important (Lee and Hoff 2002).

Fig. 3.2 Overall distribution of cations used to form salts of weak acids in the Orange Book. From Paulekuhn et al. (2007)

3.2.1 Pharmaceutical Salt Selection

Unfortunately, there are no known methods for predicting the influence of a particular counterion or class of counterions on the behavior of a drug substance (O'Connor and Corrigan 2001). While qualitative rules of thumb exist, they are oftentimes found to be unreliable. It is therefore a requirement to empirically determine the salt that exhibits essential and desirable characteristics. In previous years, salt screening involved manually mixing the ionizable drug substance with selected counterions to form salt precipitates which were then fully characterized by a variety of techniques (Kumar et al. 2007). While effective, this method provides a limited amount of data due to time and material constraints.

A number of automated high-throughput techniques have been described in the literature for the screening of pharmaceutical salts which limit the amount of drug required while providing a significant amount of data (Morris et al. 1994; Bastin et al. 2000; Morissette et al. 2004; Ware and Lu 2004; Kumar et al. 2007). Generally, techniques such as these comprise four major functional elements: sample preparation, solids generation, solids detection, and sample analysis (Morissette et al. 2004).

Most commonly, the sample preparation step consists of transferring a known amount of drug substance into multi-well plates followed by the addition of selected counterions and crystallizing solvent (Kumar et al. 2007). Various methods have been developed to prompt crystallization, including evaporation of the solvent, thermal cooling, and anti-solvent addition (Morissette et al. 2004). However, the precipitation process can be slow and, depending on the mode of crystallization, may take days to occur, as shown in Fig. 3.3. The combinatorial approach allows one to evaluate not only a large number of compositions but also crystallization conditions.

Fig. 3.3 Typical rate of appearance of solids during a thermally driven high-throughput crystallization experiment. From Gardner et al. (2004)

Sample analysis of the resulting solid is most commonly conducted using a tiered approach such that essential criteria are met prior to undertaking more time-consuming analyses, as shown in Fig. 3.4 (Kumar et al. 2007). Solids formed in the wells are normally first characterized by Raman spectroscopy and X-ray powder diffraction. Samples identified as being feasible salts are then analyzed by techniques to determine if essential criteria are met. These include hygroscopicity, solubility, and stability analyses.

After preliminary identification of viable salts through screening, production of larger quantities may be carried out to evaluate the suitability of the synthesis process and ultimately the prepared pharmaceutical salt. Care should be taken to ensure that polymorphic forms are not formed during the scale-up process.

3.2.2 Solubility Enhancement

The primary purpose of forming a pharmaceutical salt, in most cases, is to enhance the solubility of the compound and thus bioavailability. In a recent study, salts of ephedrine from a variety of counter-ions were prepared (Black et al. 2007). This study highlighted the fact that one of the most important molecular properties for the design of a salt screen is the acid and base dissociation constants (pK_a). The authors illustrated this concept by showing speciation diagrams for ephedrine and acetic acid in water Fig. 3.5a. In the pH range of 6–8, both species are predominantly present as ions, which favors salt formation ($\Delta pK_a \approx 5$). However, the researchers point out that the solvent can affect the ΔpK_a value. This is illustrated in Fig. 3.5b,

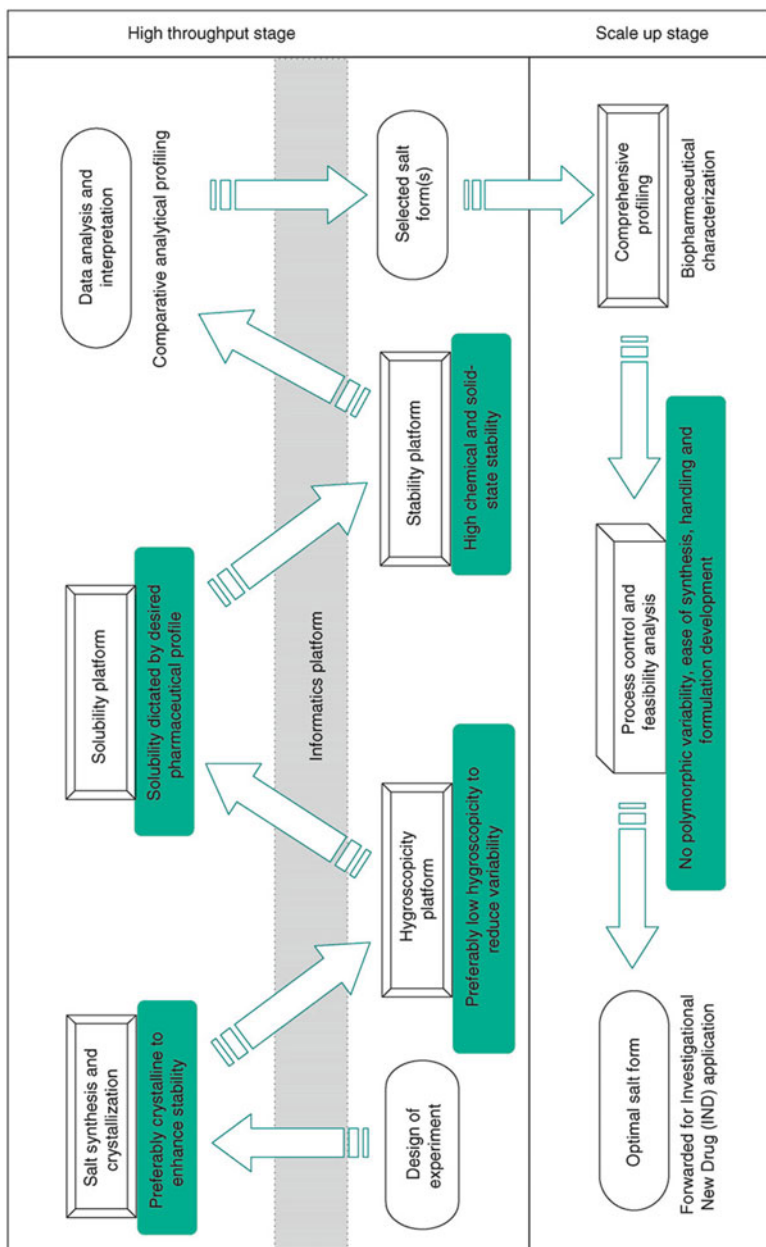

Fig. 3.4 Stages of high-throughput salt selection showing an interface with the scale-up stage of salt screening. Stages depicted with a double-lined box indicate essential criteria and the cuboidal box shows desirable criteria of salt selection with the preferable parameters depicted in the underlying shaded areas. From Kumar et al. (2007)

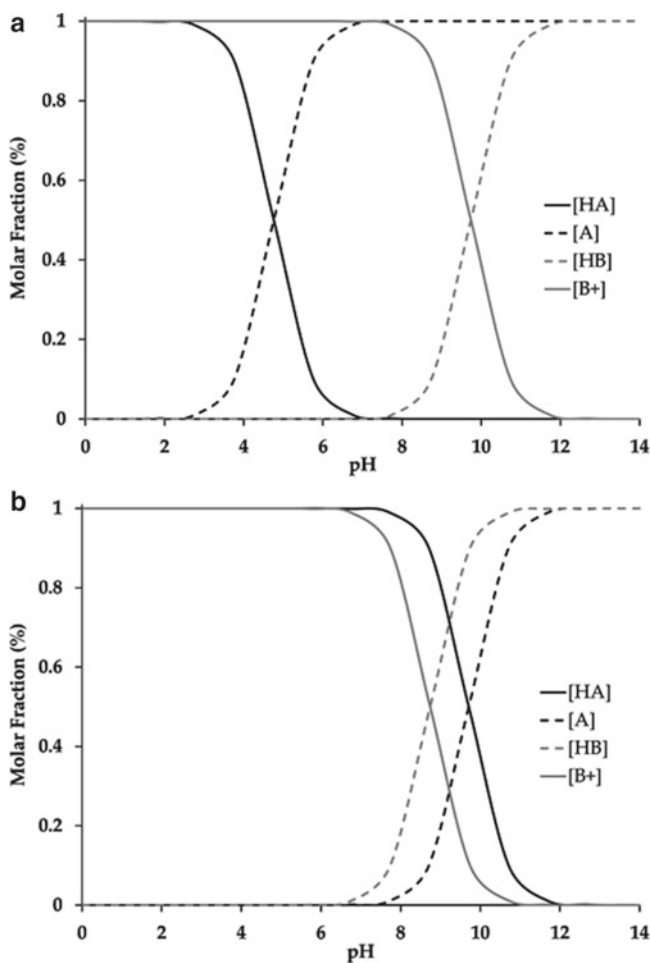

Fig. 3.5 Speciation diagrams for ephedrine and acetic acid in (a) water–ephedrine $pK_a=9.74$, acetic acid $pK_a=4.76$ and (b) methanol–ephedrine $pK_a=8.74$, acetic acid $pK_a=9.71$. Adapted from Black et al. (2007)

where the solvent was changed to methanol which resulted in a dramatic shift in the pK_a of acetic acid. In this solvent system, there is no pH range in which both ion species exist which suggests that salt formation would not occur.

Results of ephedrine crystallization showed that strong acids ($pK_a < 2$) gave salts from water and methanol, as one would expect. Weak acids ($pK_a > 3$) gave salts from water, but not from methanol which was due to the upward shift in acid pK_a . Properties of the ephedrine salts formed are detailed in Table 3.1. The researchers demonstrated that the solubility of ephedrine could be enhanced by as much as 16-fold by forming a pharmaceutical salts. Further inspection of Table 3.1 demonstrates the wide range of solubilities that can be obtained by various salts.

Table 3.1 The measured and calculated physical properties of ephedrine salts

| Salt | Molecular weight (g/mol) | Ephedrine solubility (mol/L) |
|-----------------------------|--------------------------|------------------------------|
| Free base | 165.23 | 0.345 |
| Hemihydrate | 174.24 | 0.643 |
| Acetate | 225.28 | 3.751 |
| Adipate | 311.37 | 5.299 |
| Maleate monohydrate | 299.32 | 3.792 |
| Malonate (2:1) | 434.52 | 3.392 |

Table 3.2 Comparison of the physicochemical properties of RPR200765 salt forms

| Salt | Molecular weight (g/mol) | Solubility at 25°C (mg/mL) |
|------------------|--------------------------|----------------------------|
| Free base | NA | 0.01 |
| Mesylate | 566.61 | 39.00 |
| Camphorsulfonate | 684.79 | 19.95 |
| Hydrochloride | 524.98 | 16.68 |
| Hydrobromide | 569.43 | 3.29 |

Adapted from Bastin et al. (2000)

Bastin et al. utilized a high-throughput screening technique in an effort to identify a suitable salt for a weak base (RPR 200765) that exhibited poor aqueous solubility (~10 µg/mL) (Bastin et al. 2000). The researchers demonstrated the successful formation stable salts with hydrochloride, hydrobromide, methanesulfonate (mesylate), and camphorsulfonate counterions. Results of this study, summarized in Table 3.2, demonstrated that the mesylate salt provided a significant improvement in solubility over the free base. While the mesylate salt form was found to be a monohydrate, it was nonhygroscopic and lost moisture only at very low humidity (<10% relative humidity). Furthermore, the mesylate salt exhibited good flowability. Based on the results of the study, the mesylate salt was found to be suitable for a solid dose formulation.

Table 3.3 Classification of common pharmaceutical salts

| pH of dissolution medium | Dissolution rate (mg/min) | Solubility at bulk pH (mg/mL) |
|--------------------------|---------------------------|-------------------------------|
| Free base | | |
| 1.1 | 0.032 | 0.79 |
| 2.0 | 0.246 | 3.41 |
| 3.1 | 0.061 | 4.19 |
| 5.0 | 0.002 | 2.47 |
| HCl salt | | |
| 1.1 | 0.025 | 0.79 |
| 1.5 | 0.062 | 2.50 |
| 2.0 | 0.155 | 3.41 |
| 3.1 | 0.292 | 4.16 |
| 5.0 | 0.291 | 2.47 |
| 7.0 | 0.157 | 0.02 |
| Mesylate salt | | |
| 1.1 | 0.033 | 0.65 |
| 1.7 | 0.115 | 20.76 |

| 3.1 | 2.037 | 28.45 |
| 5.0 | 1.962 | 30.44 |
| 7.0 | 1.760 | 0.002 |

Adapted from Li et al. (2005)

Li et al. conducted a comprehensive study in which the solubility and dissolution rates of haloperidol, a weak base (pK_a 8.0) with an intrinsic solubility of 2.5 $\mu\text{g/mL}$, and two of its salts (hydrochloride and mesylate) were evaluated (Li et al. 2005). While the pH solubility profiles of the free base and its hydrochloride salt were very similar, the mesylate salt exhibited much greater solubility in the pH range of 2–5, as shown in Table 3.3. Maximum solubility values for the hydrochloride and mesylate salts were found to be 4.2 mg/mL and 30.4 mg/mL, respectively. The researchers also showed that the dissolution rate of the mesylate salt was much higher than that of the hydrochloride salt or free base, except at very low pH values ($\text{pH} < 2$).

Engel et al. conducted a study to determine the most suitable salt for a weak base (LY333531) which exhibited very low aqueous solubility (1 $\mu\text{g/mL}$) (Engel et al. 2000). Without utilizing a high-throughput screening technique, the researchers evaluated seven counterions for salt formation: hydrochloride, sulfate, mesylate, succinate, tartrate, acetate, and phosphate. Of the salts prepared, only the mesylate and hydrochloride salts exhibited the essential criteria and were thus analyzed further. Aqueous solubility of the mesylate and hydrochloride salts was found to be 0.5 and 0.1 mg/mL (as LY333531), respectively, which was a substantial improvement over the free base. An in vivo study in male beagle dogs demonstrated that the mesylate salt exhibited a 250% increase in plasma concentrations of LY333531 and its active metabolite, LY338522, over that of the hydrochloride salt. The plasma concentration versus time plot for this study is shown in Fig. 3.6.

Fig. 3.6 Mean plasma concentrations of LY333531 and LY 338522 in male beagle dogs orally administered LY333531 HCl and LY333531 mesylate (20 mg LY333531/kg). From Engel et al. (2000)

The preparation of pharmaceutical salts is an effective method to enhance solubility and bioavailability of drug substances exhibiting poor aqueous solubility. A large number of counterions are available for this purpose and are capable of producing salts with significantly different physical properties. Thus, selection of the optimal salt form early in the development process is critical.

3.3 Polymorphs and Amorphous Forms

The ability of metastable forms of drug substances to enhance solubility over their thermodynamically stable counterparts has been well documented in a number of reviews (Huang and Tong 2004; Mao et al. 2005; Pudipeddi and Serajuddin 2005). Metastable systems utilized for the purpose of increasing the apparent solubility of drug substances with poor aqueous solubility include crystalline polymorphs, solvates, desolvates, and amorphous forms.

Polymorphs have been studied extensively since the early reports of their existence (Aguiar et al. 1967; Aguiar and Zelmer 1969; Haleblian and McCrone 1969). These substances are defined as having identical chemical compositions, but differ in internal structure, including unit cell dimensions and crystal packing which can affect pharmaceutical performance (Byrn et al. 1999b). These effects include solubility, rates of dissolution, bioavailability, processability, physical stability, and chemical stability. A large number of drug substances, whether they be neutral, free

acids, free bases, or pharmaceutical salts, are capable of exhibiting polymorphism (Bowker and Stahl 2008). While some compounds do not exhibit polymorphism, other may have multiple polymorphs. For example, progesterone is known to exist as five polymorphic forms, all of which have different physical and chemical properties (Byrn et al. 1999b). The polymorphic form exhibiting the highest density and melting point is considered the most thermodynamically stable form.

Pseudopolymorphs, also known as hydrates or solvates, contain molecules from the crystallization solvent within the crystal lattice (Bechtloff et al. 2001). These solvent molecules are often located in discrete crystal sites and bound within the lattice (e.g., hydrogen bonding) (Yu et al. 1998). It is possible to have both stoichiometric and nonstoichiometric forms of these substances, with the stoichiometric form being most common. Solvates, which contain a solvent other than water, are mostly nonpractical from a pharmaceutical standpoint due to potential toxicity. While hydrates are normally more stable than their anhydrous counterparts, they rarely provide any solubility advantage and, in most cases, exhibit a lower solubility. However, hydrates and solvates may be desolvated to provide solubility enhancement, albeit in a relatively thermodynamically unstable form (Yu et al. 1998).

Amorphous forms of drug substances are yet another physical modification of the solid-state which provide the greatest solubility potential. They differ from their crystalline polymorph counterparts by having low packing efficiency and lack of long-range crystalline order (Yu 2001). This results in a very high free energy and, thus, the capability to provide a substantial improvement in solubility (Hancock and Zografi 1997).

3.3.1 *Polymorph Preparation*

Polymorphic forms present a number of challenges to the pharmaceutical scientist. For drug substances that are not well-characterized early in the drug development process, polymorphs can be discovered in later stages of drug development or, in a worst-case scenario, after the drug product is marketed. Either situation can have a profound impact in terms of time and cost, meaning that a comprehensive search for polymorphic forms is justified (Yu et al. 1998). In a classic example of polymorphism, ritonavir, an HIV protease inhibitor, was found to exhibit a more thermodynamically stable polymorph 2 years after its market entry (Bauer et al. 2001). The previously unknown polymorph was found to be approximately 50% less soluble in the formulation vehicle, resulting in a substantial decrease in dissolution rate and ultimately withdrawal of the drug product from the market. A new formulation incorporating the more stable polymorph was developed and marketed (Chemburkar et al. 2000). In another example, a polymorph of carbamazepine was reported in 2002, two decades after identification of its other three polymorphic forms (Lang et al. 2002).

The process of discovering polymorphs requires extensive experimentation which is normally accomplished by high-throughput screening techniques very

similar to those used in pharmaceutical salt screening. Variables such as supersaturation, agitation rate, cooling rate, solvent composition, temperature, seed crystals, additives, and impurities are all known to affect crystallization and should be investigated (Allesø et al. 2008; Alvarez et al. 2009). By evaluating as many variables as possible, the likelihood of identifying a large majority or all of the polymorphs is high. Morissette et al. (2003) utilized a high-throughput screening study to evaluate polymorphic forms of ritonavir. Utilizing less than 2 g of drug substance, the researchers conducted 2,000 experiments. In addition to the two known polymorphs, three new forms were discovered: a metastable polymorph, a crystalline solvate, and a nonstoichiometric hydrate. This example demonstrates the clear advantage of performing extensive studies early in drug development. However, even thorough solution-based studies may not be sufficient. Peterson et al. (2002) conducted a high-throughput polymorphism screening study on acetaminophen in an attempt to generate the three known forms (forms I, II, and III). Of 7,776 crystallization trials, only 723 resulted in precipitates and of those, 29 were form II, with the remainder being form I. Melt crystallization was required to generate form III, demonstrating the need to consider alternative crystallization techniques. While comprehensive studies cannot guarantee that all polymorphic forms will be identified, they certainly provide a level of assurance that additional forms will not be easily formed.

3.3.2 *Amorphous Form Preparation*

Amorphous solids are generally more easily prepared than polymorphic forms which can require specific crystallization conditions. Techniques that may be utilized for the preparation of amorphous solids are outlined in Table 3.4. With the exception of crystal disruption, most techniques begin with solubilizing or melting the drug substance followed by solvent removal or quenching, respectively, at rates that kinetically avoid recrystallization (Hancock 2002). The result is a metastable substance with no long-range crystalline order (Table 3.4).

3.3.3 *Thermodynamics of Metastable Solids*

Metastable solids exhibit excess enthalpy, entropy, and, thus, free energy when compared to the most thermodynamically stable form (Yu 2001). Since thermodynamic stability of a solid is a function of both enthalpy (H) and entropy (S) at constant temperature (T) and pressure (P), it is important to evaluate the Gibbs free energy, G , for each system studied (Grant and Higuchi 1990). For form I of a single component system,

$$G_I = H_I - TS_I, \quad (3.1)$$

and, for form II,

Table 3.4 Methods of manufacturing molecularly disordered (amorphous) pharmaceutical materials

| From | Method | Examples |
|----------|---------------------------|--|
| Crystal | Disruption/energy input | Milling or grinding Compression or decompression Dehydration or desolvation Irradiation Reaction |
| Solution | Solvent removal | Spray-drying Freeze-drying Precipitation Polymerization Reaction |
| Liquid | Cooling or energy removal | Melt quenching Nucleation suppression Polymerization Reaction |
| Vapor | Cooling or energy removal | Sublimation Reaction |

Adapted from Hancock (2002)

$$G_{II} = H_{II} - TS_{II}. \quad (3.2)$$

Subtraction of (3.1) from (3.2), we can obtain the difference in Gibbs free energy between the forms:

$$\Delta G_{II}^I = \Delta H_{II}^I - T\Delta S_{II}^I, \quad (3.3)$$

where ΔH is a measure of crystal lattice energy differences and ΔS is the difference in disorder and lattice vibrations between the two forms (Rodríguez-Spong et al. 2004). Utilizing the relationship in (3.3), it is possible to evaluate relative differences in Gibbs free energy values.

A diagram showing Gibbs free energy versus temperature provides complete and quantitative information about the relative stability of various metastable forms and can be obtained through thermal and solution-based techniques (Yu 1995; Yu et al. 1998). The schematic in Fig. 3.7 demonstrates Gibbs free energy as a function of temperature for a hypothetical single-component system consisting of multiple metastable states. It is clear that form C exhibits the lowest free energy at all temperatures and is thus the most thermodynamically stable form. Similarly, the amorphous form exhibits a Gibbs free energy that is higher than the crystalline polymorph states, which can be attributed to a higher enthalpy and entropy, as shown in (3.3) (Hancock and Zografi 1997). The amorphous form lacks a crystal lattice and thus does not exhibit a melting point, but rather a glass transition temperature (T_g). From a kinetics perspective, an amorphous material may exist in a number of states with different properties (e.g., T_g , relaxation time, etc.) that are dependent on its mode of preparation (Shalaev and Zografi 2002).

Fig. 3.7 Schematic Gibbs free energy curves for a hypothetical single-component system that exhibits crystalline and amorphous phase transitions. Abbreviations indicate glass transition temperatures, transition temperatures, and melting temperatures for each of the systems described. From Rodríguez-Spong et al. (2004)

Further inspection of Fig. 3.7 demonstrates the behavior of two different types of polymorph systems: monotropic and enantiotropic. Forms A and C exhibit monotropic polymorphism in that form C is more stable than form A at all temperatures below their melting points. Conversely, forms A and B exhibit enantiotropic behavior in that there is a transition temperature, below that of the melting point, in which the thermodynamic stability is reversed.

Due to their high free energy, metastable solids have the potential to convert to a more metastable polymorph or to the most thermodynamically stable state through nucleation and growth. The conversion process is kinetic in nature and if the rate is slow relative to the pharmaceutical relevant time scale, the metastable form may be utilized in a drug product (Dannenfelser et al. 2004). Hancock et al. evaluated the physical stability of amorphous solids and through thermal relaxation studies determined that if the glass transition temperature of the material is at least 50°C less than the storage temperature, crystallization due to molecular mobility is not a concern over the pharmaceutical time scale (Hancock et al. 1995). It should be noted that chemical stability of metastable forms is a concern, primarily due to decreased molecular packing, potential for moisture absorption, and increased molecular mobility (Xiang and Anderson 2004). The most thermodynamically stable polymorphic form is often chosen for development which, in most cases, is

the least-soluble form (Singhal and Curatolo 2004). However, in some cases the advantages of enhanced solubility, dissolution rates, and bioavailability outweigh potential disadvantages and a metastable form is developed.

In addition to relative stability, Gibbs free energy values can be utilized to estimate relative solubility between solid forms (Parks et al. 1928, 1934). This is accomplished by recognizing that free energy is related to the activity of a compound through the following definitions:

$$G_I = RT \cdot \ln \alpha_I, \quad (3.4)$$

$$G_{II} = RT \cdot \ln \alpha_{II}, \quad (3.5)$$

where α_I and α_{II} are activities of the respective forms. Activities are a reflection of “escaping tendencies” and are thus proportional to solubility, σ (Gupta et al. 2004). By substituting the solubility terms and subtracting (3.4) from (3.5), we can obtain:

$$\Delta G_I'' = RT \cdot \ln \left(\frac{\sigma_{II}}{\sigma_I} \right). \quad (3.6)$$

Hence, the solubility ratio between two forms is shown to be proportional to Gibbs free energy.

3.3.4 Solubility and Bioavailability Enhancement

Hancock et al. utilized the relationship detailed in (3.6) to predict the relative solubility of 11 different drugs with polymorphic or amorphous forms (Hancock and Parks 2000). Through thermal-based techniques, the researchers estimated $\Delta G_I''$ at constant temperature and were able to solve for the activity (solubility) ratio, $\left(\frac{\sigma_{II}}{\sigma_I} \right)$. Data were obtained from the pharmaceutical literature for all drugs, with the exception of indomethacin which was determined experimentally. Polymorphs of indomethacin were prepared by precipitation from a saturated methanol solution with water while amorphous material was prepared by melt quenching with liquid nitrogen. Predicted solubility ratios for each of the compounds and their respective metastable forms are summarized in Table 3.5. The magnitude of the predicted solubility advantage for higher-energy polymorphs ranged from 1.1 to 3.6-fold. However, predicted solubility ratios for amorphous drug forms were significantly higher and ranged from 12 to 1652-fold due to a higher free energy in the amorphous state. The relatively low-solubility ratios for polymorphs can be attributed to small differences in free energy while amorphous systems are capable of much higher free energy values (Blagden et al. 2007).

Table 3.5 Predicted solubility ratios for drug compounds

| Compound | Forms | Solubility ratio ^a | Comment |
|---------------------------|--------------------------------------|-------------------------------|---------|
| Indomethacin | α -crystal/ γ -crystal | 1.1–1.2 | 45°C |
| | | 38–301 | 5°C |
| | amorphous/ γ -crystal | 25–104 | 25°C |
| | | 16–41 | 45°C |
| Carbamazepine | III-crystal/I-crystal | 1.7–2.1 | 2°C |
| | | 1.7–2.0 | 12°C |
| | | 1.6–2.0 | 17°C |
| | | 1.6–1.9 | 26°C |
| | | 1.6–1.8 | 40°C |
| | | 1.5–1.7 | 58°C |
| Chloramphenicol palmitate | A-crystal/B-crystal | 3.6 | 30°C |
| Iopanoic acid | II-crystal/I-crystal | 2.3–2.8 | 37°C |
| Mefnamic acid | I-crystal/II-crystal | 1.5 | 30°C |
| Glibenclamide | amorphous/crystal | 112–1652 | 23°C |
| Glucose | amorphous/crystal | 16–53 | 20°C |
| Griseofulvin | amorphous/crystal | 38–441 | 21°C |
| Hydrochlorothiazide | amorphous/crystal | 21–113 | 37°C |
| Iopanoic acid | amorphous/I-crystal | 12–19 | 37°C |
| Polythiazide | Amorphous/crystal | 48–455 | 37°C |

Adapted from Hancock and Parks (2000)

^aThe range of values reflects the use of different ΔC_p values for the calculations

Experimental solubilities were found to be significantly less than the predicted values, as shown in Table 3.6. However, all higher-energy polymorphic forms provided some degree of solubility enhancement. It is interesting to note that solubility of the amorphous forms were all noted to be much greater than those predicted or measured for the corresponding crystalline forms at all temperatures studied. The large discrepancy between predicted and experimental solubility values for the amorphous substances was attributed to a strong driving force for recrystallization in the dissolution media, as illustrated in Fig. 3.8.

A comprehensive literature review on the actual solubility ratio between polymorphs was conducted by Pudipeddi and Serajuddin (2005). In total, the authors evaluated 55 compounds which resulted in 81 solubility ratios due to the existence of multiple polymorphic forms. Overall, the average solubility ratio for the polymorphs evaluated was 1.7 (excluding the premafloxacin outlier). The solubility ratios from the literature were in agreement with and even included the data presented by Hancock and Parks (2000). These values are summarized in Fig. 3.9. Additionally, the authors evaluated 23 anhydrate/hydrate solubility ratios and found that, in general, the values were less than about two. However, there were cases in which the solubility ratio was significantly higher than this value. The anhydrate/hydrate values are summarized in Fig. 3.10.

Although relative improvements in solubility are modest between different polymorphs or pseudopolymorphs, for poorly water-soluble drugs that exhibit rate-limiting absorption, this difference may provide a significant increase in therapeutic activity.

Table 3.6 Experimental solubility ratios for drug compounds

| Compound | Forms | Solubility ratio ^a | Comment |
|---------------------------|--------------------------------------|-------------------------------|-----------------------------------|
| Indomethacin | α -crystal/ γ -crystal | 1.1–1.2 | 45°C, water |
| | amorphous/ γ -crystal | 38–301 | 5°C, water |
| | | 25–104 | 25°C, water |
| | | 16–41 | 45°C, water |
| Carbamazepine | III-crystal/I-crystal | 1.7–2.1 | 2°C, 2-propanol |
| | | 1.7–2.0 | 12°C, 2-propanol |
| | | 1.6–2.0 | 17°C, 2-propanol |
| | | 1.6–1.9 | 26°C, 2-propanol |
| | | 1.6–1.8 | 40°C, 2-propanol |
| | | 1.5–1.7 | 58°C, 2-propanol |
| Chloramphenicol palmitate | A-crystal/B-crystal | 3.6 | 30°C, 35% <i>t</i> -butanol (aq.) |
| Iopanoic acid | II-crystal/I-crystal | 2.3–2.8 | 37°C, phosphate buffer (aq.) |
| Mefnamic acid | I-crystal/II-crystal | 1.5 | 30°C, dodecyl alcohol |
| Glibenclamide | amorphous/crystal | 112–1652 | 23°C, buffer (aq.) |
| Glucose | amorphous/crystal | 16–53 | 20°C, methanol |
| | | | 20°C, ethanol |
| | | | 20°C, isopropanol |
| Griseofulvin | amorphous/crystal | 38–441 | 21°C, water |
| Hydrochlorothiazide | amorphous/crystal | 21–113 | 37°C, HCl & PVP (aq.) |
| Iopanoic acid | amorphous/I-crystal | 19-Dec | 37°C, phosphate buffer (aq.) |
| Polythiazide | Amorphous/crystal | 48–455 | 37°C, HCl & PVP (aq.) |

^aThe range of values reflects the use of different ΔC_p values for the calculations

Adapted from Hancock and Parks (2000)

In a study conducted by Kobayashi et al., the effect of crystalline carbamazepine polymorphs on solubility, dissolution rate, and oral bioavailability was investigated (Kobayashi et al. 2000). Calculated aqueous solubility values of form I, form III, and the dihydrate were found to be 460.2 $\mu\text{g/mL}$, 501.9 $\mu\text{g/mL}$, and 311.1 $\mu\text{g/mL}$, respectively. In agreement with the ranges outlined by Pudipeddi and Serajuddin, the solubility ratio between the low and high-energy polymorphic states ranged from 1.5 to 1.6 for form I and form III, respectively (Pudipeddi and Serajuddin 2005). Dissolution profiles of the three drug substances are illustrated in Fig. 3.11. Forms I and III exhibited a transient dissolution rate improvement, ultimately converting to the more stable form in solution. While form I initially provided the greatest solubility, it converted to the more stable dihydrate form relatively rapidly. However, form III exhibited sustained supersaturation which is a desirable characteristic for poorly water-soluble compounds. Each polymorphic form was evaluated for in vivo drug absorption using a crossover technique in male beagle dogs. The in vivo performance of the polymorphic forms was compared to a solubilized amorphous formulation, representing 100% bioavailability. The study demonstrated that at high dose, form I provided the greatest C_{max} and $\text{AUC}_{0-12\text{h}}$ values when compared

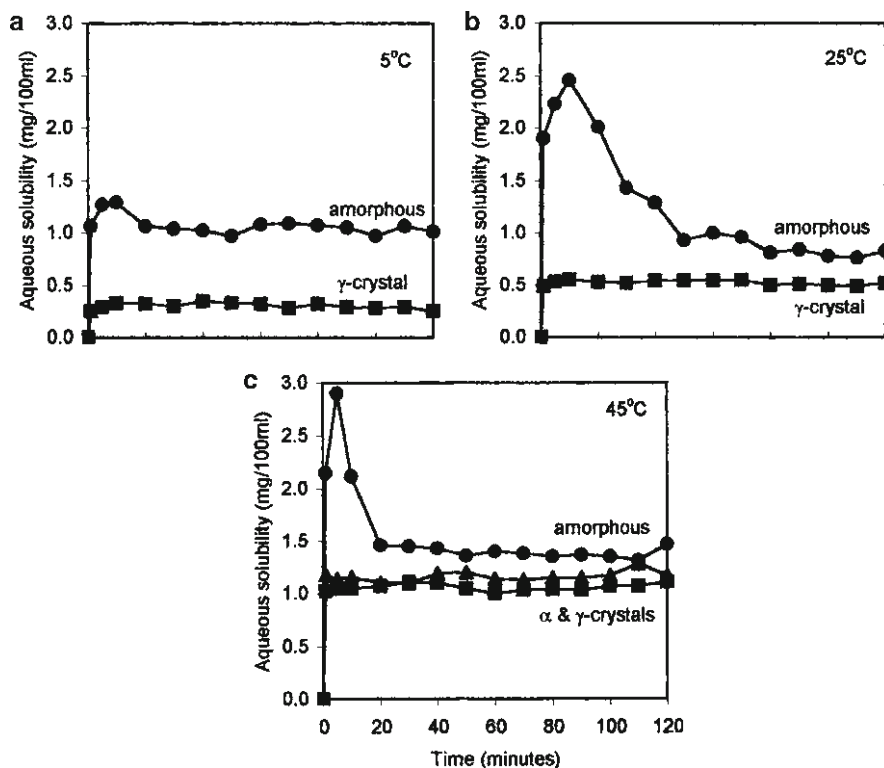

Fig. 3.8 Experimental aqueous solubility profiles for amorphous and crystalline indomethacin at (a) 5°C, (b) 25°C, and (c) 45°C. From Hancock and Parks (2000)

Fig. 3.9 Solubility ratios for polymorphs ($n=81$). The data do not include the premafloxacin (I/III) ratio which was found to be 23.1. From Pudipeddi and Serajuddin (2005)

Fig. 3.10 Anhydrate/hydrate solubility ratios ($n=23$). Compound 6 is expressed as hydrate/anhydrate due to an anomaly. From Pudipeddi and Serajuddin (2005)

to the other two forms. Bioavailability of form I, form III, and the dihydrate, relative to the amorphous solubilized formulation, was found to be 68.7%, 47.8%, and 33%, respectively. This result is consistent with the probable conversion of form III to the dihydrate form in situ. The plasma concentration versus time curve for this arm of the study is shown in (Fig. 3.12). This result indicated that while there was a very small difference in measured solubility between form I and form III, the ability of form I to remain in a supersaturated state for an extended period time allowed for improved oral bioavailability (Fig. 3.12).

In a recent study conducted by Kim et al., the oral bioavailability of amorphous atorvastatin hemi-calcium prepared by various techniques was evaluated (Kim et al. 2008). Specifically, the researchers evaluated spray-drying and supercritical anti-solvent (SAS) processes against unprocessed crystalline material with low aqueous solubility (142.2 $\mu\text{g}/\text{mL}$). Material processed by spray-drying and SAS processes, which utilized acetone or tetrahydrofuran as the solvent, exhibited aqueous solubilities ranging from 467.1 to 483.2 $\mu\text{g}/\text{mL}$. Amorphous material prepared from the SAS and spray-drying processes were found to have particle size ranges from 68.7 to 95.7 nm and 3.62 to 7.31 μm , respectively. Powder dissolution analysis revealed that amorphous material provided significant improvements in dissolution rate, as illustrated in Fig. 3.13. Amorphous particles prepared by the SAS processing method were found to have a faster rate of dissolution than those prepared by spray drying, consistent with its small particle size. Unprocessed and amorphous materials were evaluated for in vivo drug absorption in male rats. The hypothesis tested with this study was that not only would amorphous materials provide enhanced absorption, but that material prepared by SAS, due to its small particle size and

Fig. 3.13 Powder dissolution profiles of unprocessed atorvastatin particles (*filled square*), SAS-processed amorphous atorvastatin calcium precipitation from acetone (*filled circle*), SAS-processed amorphous atorvastatin calcium precipitated from a tetrahydrofuran solution (*filled triangle*), spray-dried amorphous atorvastatin calcium from an acetone solution (*empty circle*), and spray-dried amorphous atorvastatin calcium from a tetrahydrofuran solution (*empty square*) ($n=3$), (mean \pm S.D.). From Kim et al. (2008)

large surface area, would provide the highest absorption. From this study, it was determined that amorphous materials provided a significant increase in drug absorption, with SAS prepared material providing the greatest improvement. The amorphous form prepared by SAS with acetone showed a threefold improvement in the AUC_{0-8h} , a fourfold improvement in C_{max} , and a twofold improvement in T_{max} . Similarly, spray-dried amorphous material also provided a significant improvement over crystalline drug. The plasma concentration versus time curve from this study is shown in Fig. 3.14. It is clear from this study that the amorphous form can have a marked impact on bioavailability.

The use of metastable solids has been shown to be an effective method to enhance both solubility and bioavailability of drug substances. While most polymorphic forms generally provide relatively small improvements in solubility, the improvement by be significant from a pharmacological standpoint. However, these systems are inherently unstable and extreme care should be taken to ensure that crystallization into an undesirable form does not occur during processing (e.g., granulation, drying, tableting, etc.) or storage. This is particularly difficult in the case of amorphous solids, which are normally stabilized by excipients or formulated as solid dispersion systems prior to being incorporated into solid dosage forms (Leuner and Dressman 2000).

3.4 Pharmaceutical Co-crystals

Pharmaceutical co-crystals have emerged as an alternative to salts and metastable solids for the enhancement of solubility, dissolution, and bioavailability. Co-crystals are defined as a crystalline material comprised of at least two molecular species held together by noncovalent interactions (Byrn et al. 1999a). In addition to their ability to form with neutral drug substances, co-crystals may be formed with acidic, basic, or salt forms of drug substances (Schultheiss and Newman 2009). Morissette et al. described co-crystals as being structurally similar to solvates, with the primary difference being the physical state of individual components (Morissette et al. 2004). That is, the crystal may be classified as a solvate if one of the components is a liquid and a co-crystal if both of the components are solid.

While solvates are capable of providing dissolution enhancement, they are of little pharmaceutical value due to inclusion of organic solvents that are often not biocompatible. Furthermore, solvates are susceptible to desolvation which can potentially lead to recrystallization of a less-soluble polymorphic form. Compared to solvates, co-crystals exhibit a higher-degree physical stability and may incorporate innocuous co-crystal formers, the number of which is numerous (Schultheiss and

Newman 2009). While co-crystal systems have been studied for many years, their ability to improve solubility and bioavailability of poorly water-soluble drug substances has only recently been fully realized (Good and Rodríguez-Hornedo 2009).

3.4.1 *Co-crystal Preparation*

The process of determining an optimal co-crystal former for a drug substance is generally best accomplished by selection of potential co-crystal formers followed by an empirical study. High-throughput screening techniques may be utilized to cover a wide range of co-crystal formers, solvents, and crystallizing conditions (Morissette et al. 2004). Compatibility between a co-crystal former and a drug substance is highly dependent on the chemical structure of both compounds. Therefore, the first step in designing a co-crystal is to gain a detailed understanding of the functional groups present in the drug substance as this will facilitate the selection of a proper co-crystal former (Shan and Zaworotko 2008). Statistical analysis of known interactions between functional groups is accomplished with use of the Cambridge Structural Database (CSD) (Trask et al. 2005a). Hierarchies of supramolecular synthons that can occur between functional groups (e.g., carboxylic acids, amides, alcohols, etc.) have also been published by researchers in the field of crystal engineering (Fleischman et al. 2003; Bis et al. 2007; Shan and Zaworotko 2008; Shattock et al. 2008). Specific knowledge of noncovalent interactions between different types of functional groups, known as heterosynthons, allows one to apply this information to a specific crystal engineering application.

In a recent review, Shan and Zaworotko provided carboxylic acid–aromatic nitrogen, carboxylic acid–amide, and alcohol–pyridine as examples of heterosynthons that appear to facilitate the formation of co-crystals (Shan and Zaworotko 2008). The carboxylic acid–aromatic nitrogen heterosynthon and associated statistical data obtained from the CSD are illustrated in Fig. 3.15. The data for this particular heterosynthon demonstrate that it is much more likely to occur than the carboxylic acid–carboxylic acid homosynthon.

Porter et al. discovered a polymorphic form of the carbamazepine–saccharin co-crystal in a study evaluating a crystallization in the presence of polymer heteronuclei (Porter III et al. 2008). The widely known carbamazepine–saccharin co-crystal (Form I) was shown to incorporate a homosynthon between carbamazepine molecules (Fig. 3.16) while the newly discovered form (Form II) contained a heterosynthon between carbamazepine and saccharin (Fig. 3.16). In form I of the co-crystal, molecules were found to pack in such a way that the homosynthon formed between two inversion-related carbamazepine carboxamide groups, as shown in Fig. 3.17a. As demonstrated in Fig. 3.17b, the primary feature of form II is a different packing due to heterosynthon interactions.

Selection of a suitable co-crystal former will be highly dependent on the specific drug substance and its associated functional groups that allow for noncovalent interactions. However, selection should adhere to substances that have been previously

Fig. 3.17 Molecular packing for (a) carbamazepine–saccharin form I and (b) carbamazepine–saccharin form II. From Porter et al. (2008)

Other techniques described in the literature for the preparation of co-crystals include solid-state grinding, solvent-mediated solid-state grinding, and, to a much lesser extent, melt crystallization and sublimation (Medina et al. 2010). Solution crystallization and solid-state grinding represent the two methods that are scalable from a pharmaceutical manufacturing standpoint.

Solvents utilized in solution crystallization must be chosen carefully such that all components (e.g., drug substance and co-crystal former) completely dissolve without interfering with the interactions necessary for co-crystal formation (Morissette et al. 2004). The drug substance and co-crystal former should also have similar solubility in the chosen solvent such that a co-crystal precipitates prior to any individual component (Blagden et al. 2007).

In the solid-state, stoichiometric amounts of the drug substance and co-crystal former can be ground in order to form co-crystals (Etter et al. 1993, Kuroda et al. 2002). The driving force of co-crystal formation is often the stronger hydrogen bonds in the co-crystal than those present in the crystals of either pure component (Etter et al. 1993). Medina et al. recently described the utility of twin-screw extrusion as a method to prepare co-crystals without the use of additional solvent (Medina et al. 2010). The dry grinding process has been modified somewhat to include a small amount of solvent to enhance kinetics and facilitate the formation of co-crystals (Trask et al. 2004; Trask et al. 2005a; Trask et al. 2005b).

While many co-crystals can be prepared by solvent crystallization and solid-state grinding, some can only be prepared by a specific technique. Etter and Admond described systems that could only be prepared by co-grinding (Etter and Admond 1990). Conversely, Etter et al. described another situation where a co-crystal could be formed by solution crystallization but not by solid-state grinding (Etter et al. 1993). However, oftentimes the co-crystal obtained is independent of the processing technique utilized (Shan and Zaworotko 2008).

3.4.2 Solubility of Co-crystals

Itraconazole is a weak base that exhibits poor solubility in both acidic and neutral environments (Miller et al. 2008). Due to its poor water solubility characteristics, itraconazole is marketed as a solid dispersion in which the drug is molecularly dispersed in a hypromellose-based matrix. Remenar et al. utilized a co-crystal approach in an attempt to improve solubility and dissolution rates of this compound (Remenar et al. 2003). Succinic acid, malic acid, and tartaric acid were successfully utilized as co-crystal formers in a solvent crystallization process. Through hydrogen bonding, each co-crystal contained two molecules of itraconazole and one co-crystal former, as shown in Fig. 3.18. Dissolution in 0.1 N HCl was studied to assess relative differences of Sporanox[®], crystalline itraconazole-free base, and co-crystals of itraconazole, with results shown in Fig. 3.19. The co-crystal formed with malic acid provided a dissolution profile similar to that of Sporanox[®] beads, with solubility improving by a factor of 20-fold over the free base.

Hickey et al. prepared co-crystals of carbamazepine, a poorly water-soluble drug substance, and evaluated their performance against the marketed drug product, Tegretol[®] (Hickey et al. 2007). Utilizing a solvent crystallization process, the researchers prepared co-crystals of carbamazepine with saccharin (Form I) which exhibited the crystal packing that was previously discussed (Fig. 3.17a). To compare the performance of carbamazepine co-crystals to Tegretol[®], an in vivo study was conducted in fasted beagle dogs. The co-crystal formulation exhibited a higher AUC and C_{\max} value than Tegretol[®] with a comparable T_{\max} . The plasma concentration versus time plot for this study is shown in Fig. 3.20.

Fig. 3.18 Co-crystal of two itraconazole molecules and a single co-crystal former. From Remenar et al. (2003)

Fig. 3.19 Itraconazole dissolution profiles of Sporanox® beads (*square*), crystalline itraconazole-free base (*diamond*), and co-crystals of itraconazole with L-malic acid (*upside down triangle*), L-tartaric acid (*circle*), and succinic acid (*triangle*). Dissolution media: 0.1N HCl at 25°C. From Remenar et al. (2003)

Fig. 3.20 Average plasma-time curves of carbamazepine concentration (\pm S.E.) from a crossover experiment in fasted beagle dogs ($n=4$) given oral doses of 200 mg of the active drug as Tegretol® tablets and carbamazepine-saccharin co-crystal. From Hickey et al. (2007)

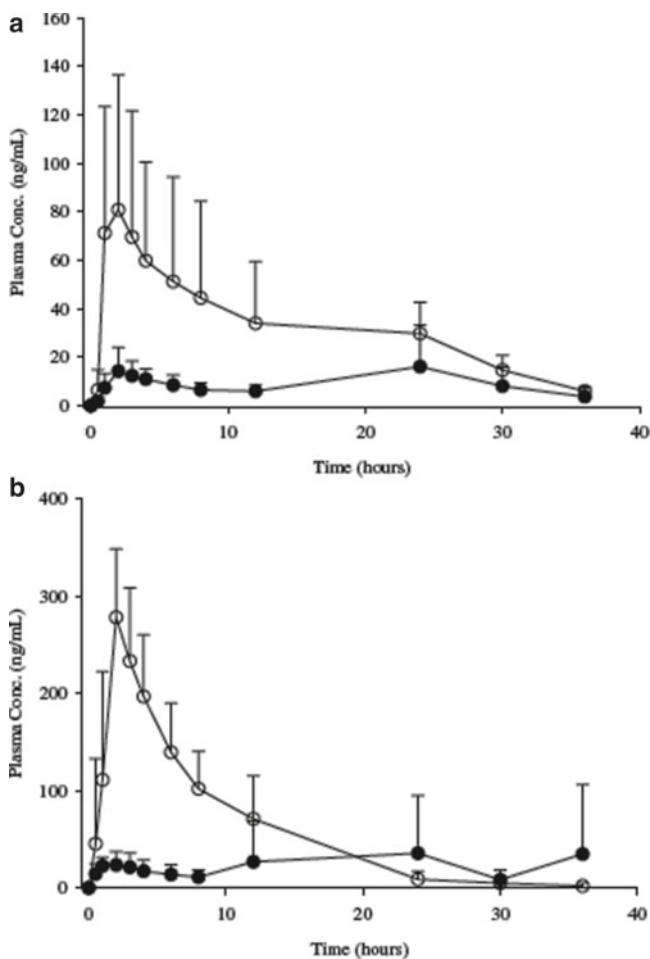

Fig. 3.21 Dog plasma concentration with time for (a) 5 mg/kg dosing of drug substance (*closed circles*) and co-crystal (*open circles*) and (b) 50 mg/kg dosing of drug substance (*closed circles*) and co-crystal (*open circles*). Adapted from McNamara et al. (2006)

McNamara et al. showed that co-crystals of a development candidate drug could be formed at a 1:1 ratio with glutaric acid (McNamara et al. 2006). The co-crystal exhibited an 18-fold improvement in solubility over the crystalline form of the drug substance. The in vivo performance of the co-crystals was compared to bulk drug substance in beagle dogs. From this study, it was determined that at low dose (5 mg/kg) and high dose (10 mg/kg), the co-crystal formulation exhibited the highest C_{max} and AUC_{0-36h} when compared to the bulk drug substance. The plasma concentration versus time plots for the low-dose and high-dose study are shown in Fig. 3.21.

The formation of co-crystals allows for the opportunity to readily modify solid-state properties of a drug substance, resulting in forms that have improved clinical significance. The co-crystal approach is particularly useful for neutral drug substances or those that do not easily form stable salts. While in its infancy in the pharmaceutical industry, the co-crystal approach is rapidly gaining interest and has the potential to largely impact the successful preparation poorly water-soluble drug substances.

3.5 Summary

Solid-state modifications address the strong intermolecular interactions responsible for poor aqueous solubility by taking advantage of properties inherent to specific drug substances. In doing so, solubility can be enhanced by a large degree allowing for improved clinical relevance. The solid-state techniques that have been described in the literature include the formation of salts, metastable solids, and co-crystals. Each technique has specific advantages that make it amenable to certain applications. Due to the nature of each technique, selection of optimal systems is often empirical and requires the use of efficient screening techniques. However, if applied properly, solid-state techniques are capable of improving the clinical relevance of many poorly water-soluble drug substances.

Method Capsule 1

Preparation of Amorphous Solids - Spray-Drying

Based on the method reported by Kim et al. (2008).

Objective

- To obtain an amorphous drug substance by the spray-drying technique

Equipment and Reagents

- Atorvastatin calcium
- Acetone or tetrahydrofuran
- Laboratory-scale spray-dryer

Method

- Dissolve atorvastatin calcium in acetone or tetrahydrofuran at a concentration of 100 mg/mL.
- Set the drying air flow rate to 0.70 m³/min.
- Set the inlet temperature of the spray dryer to 70°C.
- Feed the solution into the spray dryer at 3 mL/min with an atomization pressure of 10 kPa.
- Ensure that the outlet temperature is in the range of 62–65°C.
- Collect the dried powder.

Results

- Laser diffraction analysis revealed that the particle size of atorvastatin calcium spray-dried from acetone and tetrahydrofuran was $3.62 \pm 0.15 \mu\text{m}$ and $7.31 \pm 0.21 \mu\text{m}$, respectively.
- BET specific surface area analysis demonstrated that the surface area of atorvastatin particles spray-dried from acetone and tetrahydrofuran was $3.69 \pm 0.06 \text{ m}^2/\text{g}$ and $0.95 \pm 0.03 \text{ m}^2/\text{g}$, respectively. The specific surface area of unprocessed material was $14.56 \pm 0.17 \text{ m}^2/\text{g}$.
- Differential scanning calorimetry and X-ray diffraction analyzes indicated that all spray-dried material lacked crystalline character and was amorphous.

Method Capsule 2**Preparation of Amorphous Solids - Supercritical Anti-solvent Processing**

Based on the method reported by Kim et al. (2008).

Objective

- To obtain an amorphous drug substance by supercritical anti-solvent (SAS) processing.

Equipment and Reagents

- Atorvastatin calcium
- Acetone or tetrahydrofuran
- Laboratory-scale supercritical anti-solvent processor
- Carbon dioxide (CO_2)

Method

- Deliver CO_2 into particle formation vessel equilibrated at 40°C until the pressure reaches 12 MPa.
- Dissolve atorvastatin calcium in acetone or tetrahydrofuran at a concentration of 100 mg/mL.
- The drug solution and supercritical CO_2 were co-injected through a two-flow nozzle at 0.5 g/min and 45 g/min, respectively.
- After the drug solution was exhausted, fresh CO_2 was cycled into the vessel to remove residual solvent at 45 g/min.

Results

- Laser diffraction analysis revealed that the particle size of SAS-processed atorvastatin particles from acetone and tetrahydrofuran was $68.7 \pm 15.8 \text{ nm}$ and $95.7 \pm 12.2 \text{ nm}$, respectively. Particle size of the unprocessed material was $3.83 \pm 0.08 \mu\text{m}$.

- BET-specific surface area analysis demonstrated that the surface area of SAS processed atorvastatin particles from acetone and tetrahydrofuran was $120.35 \pm 1.40 \text{ m}^2/\text{g}$ and $79.78 \pm 0.93 \text{ m}^2/\text{g}$, respectively. The specific surface area of unprocessed material was $14.56 \pm 0.17 \text{ m}^2/\text{g}$.
- Differential scanning calorimetry and X-ray diffraction results indicated that all spray-dried material lacked crystalline character and was amorphous.

Method Capsule 3

Preparation of Amorphous Solids - Melt Quenching

Based on the method reported by Hancock and Parks (2000).

Objective

- To obtain an amorphous drug substance by melt quenching.

Equipment and Reagents

- Indomethacin
- Liquid nitrogen

Method

- Heat indomethacin to a temperature that induces melting ($\sim 160^\circ\text{C}$).
- Quench the melt with liquid nitrogen such that indomethacin solidifies.

Results

- Differential scanning calorimetry and X-ray diffraction results indicated that melt-quenched material lacked crystalline character and was amorphous.

Method Capsule 4

Preparation of Co-crystals - Temperature-Induced Precipitation

Based on the method reported by Hickey et al. (2007).

Objective

- To obtain a co-crystal of carbamazepine and saccharin by temperature-induced precipitation.

Equipment and Reagents

- Carbamazepine
- Saccharin
- Ethanol
- Methanol
- Water-jacketed glass crystallization vessel

Method

- Anhydrous carbamazepine (0.089 mol) and saccharin (0.089 mol) were combined in the crystallization vessel.
- Solids were dissolved in 280 mL of a 62.5/37.5% (v/v) ethanol/methanol, mixture and heated to 70°C for 1 h under reflux.
- Temperature was decreased in 10°C increments while stirring to induce precipitation.
- Following equilibration at 30°C, solids were isolated using a Buchner funnel and rinsed with cold ethanol.
- The resulting powder was air-dried.

Results

- A product yield of 76% was obtained.
- Microscopy studies showed that the particle size of the crystals was between 500 and 1,000 μm .
- X-ray powder diffraction and differential scanning calorimetry studies demonstrated that a single polymorphic co-crystal form was prepared.

Method Capsule 5**Preparation of Co-crystals - Seed-Induced Precipitation**

Based on the method reported by McNamara et al. (2006).

Objective

- To obtain co-crystals of a new drug candidate (compound 1) with glutaric acid by seed-induced precipitation.

Equipment and Reagents

- Compound 1
- Glutaric acid
- Chloroform
- Water-jacketed glass crystallization vessel

Method

- Compound 1 (8.431 mmol) and glutaric acid (8.410 mmol) were dissolved in boiling chloroform with stirring.
- The solution was concentrated by continued boiling until the volume was 50 mL.
- Co-crystal seeds (generated in thermal experiments) were introduced into the hot solution.
- After crystallization began, the solution was cooled over a 15 min period.
- Approximately 100 mL of cyclohexane was added and the solution was cooled on ice for 30 min.

- The co-crystal was isolated by filtration.
- The resulting powder was air-dried.

Results

- A product yield of 92% was obtained.
- The volumetric median diameter $D_{v(0.5)}$ and that of the 90th percentile $D_{v(90)}$ were found to be 49 μm and 131 μm , respectively.
- X-ray diffraction analysis showed a unique pattern that was distinguished from compound 1 and glutaric acid.
- Differential scanning calorimetry experiments indicated that the co-crystal exhibited a melting point different from that of compound 1 or glutaric acid.

Method Capsule 6

Preparation of Co-crystals - Grinding

Based on the method reported by Trask et al. (2004)

Objective

- To obtain co-crystals of caffeine and glutaric acid by a solid-state grinding technique.

Equipment and Reagents

- Anhydrous caffeine
- Glutaric acid
- Optional non-polar solvents: *n*-hexane, cyclohexane, or heptane
- Optional polar solvents: chloroform, dichloromethane, acetonitrile and water
- Ball grinder/mill

Method

- Equimolar amounts of caffeine and glutaric acid were combined in a stainless steel grinding jar.
- Optional: Add four drops of either a non-polar solvent or a polar solvent.
- Grind the materials together.
- Allow any residual solvent to evaporate.

Results

- X-ray diffraction analysis demonstrated that co-crystals were formed when the material was prepared in the absence of solvent and with non-polar or polar solvents.
- Form I of the co-crystal was found to form when no solvent or a non-polar solvent was used.
- Form II was predominantly formed when a polar solvent was used.

Chapter 4

Mechanical Particle-Size Reduction Techniques

Javier O. Morales, Alan B. Watts, and Jason T. McConville

Abstract With the increasing number of new drug candidates, the number of entities with poor aqueous solubility is on the rise. To overcome this limitation, a common formulation approach has been to decrease the particle-size of the drug. This strategy results in increased surface area, increased saturation solubility, and decreased the diffusional distance, all of which lead to an increase in the extent and the rate of dissolution. Mechanical techniques to decrease the particle-size of solids are generally classified in three categories: dry-milling, wet-milling, and high-pressure homogenization. In order to produce particles in the submicron (nano) range and further increase solubility, techniques such as wet-media milling, piston-gap homogenization, and microfluidization have been developed. All these different approaches will be reviewed and discussed in this chapter.

4.1 Introduction

The percentage of newly discovered drugs that have poor water solubility has been trending upward, and products under development in the pharmaceutical industry include approximately 40% poorly water-soluble compounds (Lipinski 2000). Of the total of drugs in the pipeline, up to 60% are derived directly from synthesis (Gribbon and Andreas 2005; Lipinski et al. 1997). Aside from the most notable limitation, i.e., poor bioavailability, these compounds are hard to formulate due to a number of other factors such as fed versus fasted bioavailability variation, lack of dose–response proportionality, suboptimal dosing, use of problematic excipients (such as cosolvents),

use of extreme basic or acid conditions to optimize solubilization, uncontrollable precipitation after dosing, and inconvenience of the dosage form (Merisko-Liversidge and Liversidge 2008). Over the years, a number of different strategies have been developed in order to overcome these limitations. Some of these efforts include creating salts, prodrugs, and screening for more soluble analogs. However, these efforts have achieved limited success and the need of novel strategies has been the driving force for the development of technologies to improve the bioavailability-related outcomes of poorly water-soluble drug molecules. Extensive research into the development of novel techniques to engineer micron-scale particles to the nanoscale range has translated into various proprietary technologies. There are five FDA-approved products based on the NanoCrystal® technology developed by Elan Drug Technologies, which is a high-energy media milling technique (Elan Drug Technologies – Commercialized Products 2010), and one based on the Insoluble Drug Delivery Microparticle technology (IDD-P®) by SkyePharma (SkyePharma – Insoluble Drug Delivery Platform 2010). Recently, the first injectable formulation using NanoCrystal® technology, Xeplion®, was approved for use in Europe.

Nonspecific formulation approaches are applicable to almost any drug molecule (apart from a few exceptions). Micronization has been for many years the most widely used nonspecific approach, which consists of converting relatively coarse drug particles to micrometer particles with a mean diameter in the range of approximately 2–5 μm and a corresponding size distribution approximately between 0.1 and 20 μm (Muller et al. 2006). Nonetheless, many novel drugs are so poorly soluble that a further decrease in particle-size is required in order to obtain acceptable solubility. Particle-size reduction techniques increase the surface area leading to an increase in the solubility by mechanisms that will be explained in this chapter. An increase in solubility is one of the reasons for reducing the particle-size of pharmaceutical powders; however, particle-size reduction is also applied in other fields of the pharmaceutical sciences, such as pulmonary drug delivery, solid oral dosages, and powder handling.

It is known in the literature that pulmonary drug delivery by dry powder inhalation is an administration route where particle-size reduction is required to reach the target region of the lung. The aerodynamic diameter of a particle should be in the critical range of 0.5–5 μm (Clark and Shire 2000) to reach appropriate regions of the deep lung for maximum absorption (Hassan and Lau 2010). This size range can be achieved by many of the various milling technologies (Chow et al. 2007).

Additionally, many pharmaceutical processes involving powders can be improved by homogenizing the particle size of the drug and excipients. Solids produced by uncontrolled crystallization or precipitation processes can have a broad size distribution that can result in poor flow properties or tendency to segregate. Blending, compressibility, flow/suspension behavior, and compaction performance can all vary with a heterogeneous particle size distribution (Fisher, 2006). Furthermore, the particle size distribution of very potent drugs, requiring low content in the final dosage form, are usually homogenized before blending with excipients in order to provide adequate content uniformity (Clement and Purutyan 2002; Rohrs et al. 2006).

Bulk active pharmaceutical ingredient (API) production may often be limited by specified particle-size profiles to meet the need of formulation and pharmaceutical processes. The capability to control the particle-size during early stage API development and to predict the operating conditions that will produce that particle-size reproducibly at commercial scale is very important. Furthermore, a final milling process may be required in order to homogenize the particle-size among batches, narrow a size distribution so that better flow and handling properties are produced, or match API particle-size more closely with excipient particle-size to minimize the potential for segregation during blending (Fisher 2006).

4.2 Rationale Behind the Reduction of Particle-Size

As stated earlier, a decrease in particle-size to the few micron range and down to the nanosize range can increase the extent and rate of solubility of drugs. This is of high relevance for poorly water-soluble compounds since this feature is their main limitation. Decreasing the particle-size to the micron range increases substantially the exposed surface area of a determined amount of powder. The micronized powder can then be further engineered, and its particle-size further decreased to the nanosize range, when the surface area increases sharply as can be depicted in Fig. 4.1. (Merisko-Liversidge and Liversidge 2008).

This has a direct effect on the dissolution rate according to the Noyes–Whitney equation as depicted in (4.1) (Noyes and Whitney 1897):

Fig. 4.1 The plot demonstrates the increase in surface area obtained when solids are fractured from the micrometer-size range to the nanometer-size range (Merisko-Liversidge and Liversidge 2008)

$$\frac{dm}{dt} = \frac{DA_s(C_s - C)}{h_H} = kA_s(C_s - C), \quad (4.1)$$

where, m is the undissolved solids' mass, t the time, h_H the diffusion boundary layer thickness, D the diffusion coefficient, k the intrinsic dissolution constant, A_s the surface area of the dissolving solid, C the concentration of solute in solution, and C_s the saturation solubility. This translates into three main factors that can affect the dissolution rate: surface area, saturation solubility, and diffusional distance.

The Kelvin equation describes the increase in vapor pressure as a function of the curvature of liquid droplets, which ultimately translates into an increase in the saturation solubility as seen in (4.2) (Simonelli et al. 1970):

$$n \frac{P_r}{P_\infty} = \frac{2\gamma V_m}{rRT}, \quad (4.2)$$

where, P_r is the vapor/dissolution pressure with particle radius r ; P_∞ is the vapor/dissolution pressure with infinite particle-size; γ is the interfacial tension; V_m is the molar volume; R is the gas constant; T is the absolute temperature; and r is the particle radius. When the particles are suspended in a saturated solution, it can be assumed that the P_r/P_∞ ratio can be approximated to the ratio of the respective activities of small and large particles. Furthermore, if the activity coefficients of both particles are equal, the activities can be replaced by their respective solubilities. Similar to the sharp increase in surface area observed for very small particle-size, reducing the particle-size below the size threshold of 1–2 μm leads to a distinct increase in the dissolution pressure, thus shifting the solubility equilibrium toward an increased saturation solubility. This is expressed in the Ostwald–Freundlich (4.3). (Simonelli et al. 1970):

$$\ln \frac{C_{s,r}}{C_{s,\infty}} = \frac{2\gamma V_m}{rRT}, \quad (4.3)$$

where, $C_{s,r}$ and $C_{s,\infty}$ are the solubilities of a particle of radius r and of a very large particle (or an approximately flat surface with very low dissolution pressure), respectively.

An additional factor that enhances the dissolution velocity is a decrease in the diffusion distance at very small particle-size as is described in the Prandtl boundary layer, (4.4). (Bisrat and Nyström 1988), which translates into an increase in the concentration gradient ($C_s - C$):

$$h_H = k \left(\frac{L^{1/2}}{v^{1/2}} \right), \quad (4.4)$$

where h_H is the diffusion boundary layer thickness, L is the length of the surface in the direction of flow, k denotes a constant, and v is the relative velocity of the flow-

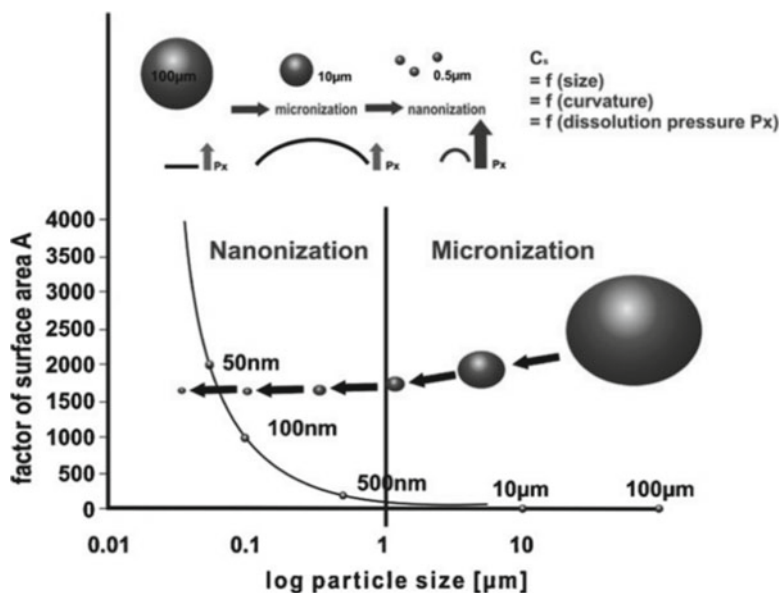

Fig. 4.2 Changes in properties when decreasing the particle-size from the micro- to the nano-range. *Top insert:* Decreasing the particle-size increases the particle-size and therefore increases the dissolution pressure, increasing the saturation solubility. *Bottom figure:* Decreasing the particle-size results in an increase in surface area, being pronounced below 1 μm and very pronounced below 100 nm (Shegokar and Müller 2010)

ing liquid against the flat surface. In addition to the above statement, this can be extracted from the Prandtl equation, where individual particles will have a very small surface exposed in the direction of the flow, which will ultimately decrease the distance that the molecules need to diffuse going into the bulk of the solution.

The equations presented here are clear evidence that reducing the particle-size results in larger surface area, elevated saturation solubility, a decrease in the diffusional distance for drug molecules, and therefore a faster rate of dissolution as summarized in Fig. 4.2.

Additionally, high-energy processes, such as those used in top-down methods for particle-size reduction, can be associated with transitions from the crystalline state to an amorphous state (Muller et al. 2003). Transformations to the amorphous state or to different polymorphs have also been observed during high-energy input processes, such as tableting (Chan and Doelker 1985; Koivisto et al. 2006; Zhang et al. 2004). High-pressure homogenization is a commonly used top-down process to obtain micro- and nanoparticles and is one such high-energy process; the drug particles are exposed to a power density of up to 10^{13} W/m^3 (Muller et al. 2003). This high-energy breaks down the drug particles into microparticles and into nanoparticles and can also induce the change to an increased amorphous fraction or to completely amorphous particles (Böhm et al. 1998; Dong and Feng 2007; Jacobs et al. 2000; Ward

Fig. 4.3 Schematic representation of a crystalline surface before and after mechanical comminution. After milling, the surface that has been exposed to collisions is disrupted and may exhibit amorphous domains (Ward and Schultz 1995)

and Schultz 1995) (Fig. 4.3). It is known in the literature that the amorphous state yields a higher saturation solubility than that exhibited by the crystalline structure of the same drug (Agrawal et al. 2004; Hancock and Parks 2000; Murdande et al. 2010). Considering the solubility enhancement inherent in the decrease in particle-size discussed earlier, amorphous nanoparticles may exhibit very high saturation solubility compared to the crystalline form prior to processing.

Furthermore, decreasing the particle-size of drugs can increase the stability of formulations. An example of this can be found in nanosuspension formulations of paclitaxel. Paclitaxel is a highly water-sensitive molecule that when dissolved in water degrades to an extent of 80% within 25 min (Liversidge et al. 2003). It has been found that the production of an aqueous nanosuspension can increase the stability over a period of 4 years when stored at 4°C, i.e., more than 99% of the drug remains intact after recovery (Troester 2004).

The following sections will discuss the theory and applications of various top-down techniques used in the field for decreasing the particle-size of drugs. These techniques can be divided into two main groups: milling and high-pressure homogenization.

4.3 Milling

Milling processes can be divided into dry or wet milling depending on the media in which the powders are milled, namely gas or liquid. In both cases, particle-size reduction occurs by collision of particles with the surfaces of the equipment as well as with each other. The collision events involve compression, impact and attrition, and cutting or shear as the main mechanisms for particle-size reduction (Clement and Purutyan 2002; Friedrich 2001; Spencer and Dalder 1997). Additionally, the wet-milling process also involves liquid shear forces or cavitation, ultimately resulting in particle-size reduction (Rabinow 2004; Sharma et al. 2009).

The density of solids in the mill is an important parameter directly affecting breakage mechanisms. Density has a direct relationship with the number of particle–particle or particle–wall collisions as well as the force of the collisions (Bentham et al. 2004). Feed rate to the mill and mill residence time also directly affect the solids' concentration in the mill. Thus, an understanding of the particle density in the mill is crucial since it can impact the milling rate and efficiency (Tangsathitkulchai 2003), both of which are important for scale-up purposes. For example, Tangsathitkulchai (2003) found that by increasing concentrations from 30 to 55% solids (by volume), the mill net power increased with increased powder filling, and then decreased after an optimum value was achieved.

Due to the nature of the milling process, the milled powders produced always exhibit a range of particle sizes or a characteristic particle-size distribution. In many cases, this range of particle sizes obeys a log normal distribution; however, some processed powders can exhibit multimodal distributions. Therefore, when the goal of milling is to meet a specific particle-size range, a classification step may be needed. Several mills available in the market can perform both operations (particle-size reduction and classification) in sequential steps in one instrument (Fisher 2006; Steckel et al. 2006). The influence of the feed particle-size can be diminished when the milling equipment includes internal classification or if a separate classifier is part of the process line. Additionally, the solids' feed rate and the intrinsic density of the particles play a fundamental role in the intensity of the interparticle collisions; therefore, controlling both factors will determine particle-size distributions and reproducibility in a given milling process.

Another parameter that is relevant to consider is the target and achieved surface area during the milling process. As stated earlier, decreasing the particle-size of a solid increases the overall surface area exposed, affecting dissolution performance. Even so, since the value of surface area is a scalar quantity representing the totality of the processed powder, it does not provide a sense of the range of particle sizes. Therefore, in the development of controlling parameters during the milling process, determining the particle-size distribution is crucial for the performance of the engineered powder. It is normally recommended to control for particle-size distribution alone, instead of surface area together with distribution since they are so closely related (Clement and Purutyan 2002).

Even though understanding the equipment capabilities and the mechanism of particle-size reduction is critical in selecting the appropriate mill, specific powder properties such as hardness, friability, and fracture toughness will affect the milling performance in both dry and wet milling equipment alike (Chaumeil 1998; Kesisoglou et al. 2007). It is common for milling equipment to be described in terms of the particle sizes that can be achieved, and for this purpose, the Mohs scale is used as an indicator of particle hardness and for estimating the mill performance (Clement and Purutyan 2002). This scale ranges from a hardness of 1 for soft materials to a value of 10 for the hardest material (diamond). Additionally, particle morphology or aspect ratio can affect milling results in various ways. For example, it has been shown that β -succinic acid crystals with plate-like morphology are more prone to crystallinity loss on milling compared to those with needle-like morphol-

ogy (Chikhalia et al. 2006). Therefore, a thorough understanding of the properties of the solid, together with the specific mechanism of particle-size reduction of the milling equipment, is of high importance.

One of the most relevant limitations of milling is to actually control and narrow the particle-size distribution; this is normally optimized by controlling for several parameters in the process. In general, capital costs for installation are high, and the operation of the equipment can be labor intensive (Fisher 2006). Additionally, while milling can allow for a reduction of the aspect ratio, it is not normally able to control the particle shape. Furthermore, some active pharmaceutical ingredients may not be able to be processed through milling due to either compaction sensitivity (losing crystallinity), temperature sensitivity (melting or changing to a different polymorph), or changing hydration state (Peltonen and Hirvonen 2010; Shoyele and Cawthorne 2006). Therefore, depending on the API characteristics, milling may not always be the best choice to reduce the particle-size of powders.

It is relevant to note that wet mills such as rotor–stator media mills (Netzsch Pumps North America, LLC, Exton, PA) or dry mills such as jet mills (Retsch GmbH, Haan, Germany) are limited in the production of solid particles in the nanometer scale (Muller et al. 2006). For example, it has been found that usual range of particles in a jet mill can be from 0.1 to 20 μm , with only a 10% in the submicron range (Muller et al. 1995). On the other hand, nanoparticles have been obtained by using ball media mills for extended periods of time (Liversidge et al. 1992; Merisko-Liversidge et al. 1996; Merisko-Liversidge et al. 2003). The following sections focus on several dry- and wet-milling techniques, describing important parameters, particle-size ranges, and applications of each technique.

4.3.1 Dry Milling

As mentioned above, particle-size reduction in dry mills occurs by pressure, friction, attrition, impact, or shearing by particle–particle or particle–equipment interactions. Even though a variety of mills are available for decreasing the particle-size, some common issues can be identified. In general, issues related to the dry-milling process may include powder accumulation that can impact performance and electrostatic agglomeration of milled particles that may hinder the API dispersion during formulation (de Villiers 1995; de Villiers and Tiedt 1996). Furthermore, the moving parts of some dry mills can generate considerable frictional heat. For example, during powder processing in a pin mill, the internal temperatures can reach 40–60°C (Fisher 2006), which can impose a limitation to certain pharmaceuticals. For these types of powders, cryomilling could be an option and is discussed in further detail later in this chapter.

In the scale-up process, the flow properties of the dry powder being deposited into the mill could affect uniformity of delivery. Furthermore, if the milled or partially milled product is very cohesive (either inherently or due to electrostatic charge), it could accumulate, and the overall process yield could be reduced. Removing the product periodically from low flow areas (cyclones, pipe elbows, and

Fig. 4.4 Scheme of a fluidized bed air jet mill (Godet-Morand et al. 2002)

bends) can increase the cost and extend the processing time. If material were to accumulate in the mill, especially in places that could block the exit of the mill, this could result in equipment overheating and eventual failure.

Manufacturers of mills normally report the correlation between particle hardness (on the Mohs scale) and the extent of size reduction that could be achieved in a particular mill. A general lower limit can be described for mills, depending on the mechanism of action and the amount of energy that it can provide for grinding. The following sections describe the dry-milling equipment used for decreasing the particle-size of pharmaceutical powders (Clement and Purutyan 2002; Fisher 2006; Friedrich 2001).

4.3.1.1 Fluidized Bed Jet Milling

The primary mechanism of particle-size reduction in the impinging jet or fluidized bed jet mill is particle–particle collisions. When the media to be milled is fed to the chamber, it is exposed to impinging high-velocity gas jets that allow for the collisions (Fig. 4.4). This type of milling equipment can process hard materials (Mohs scale hardness of up to 10), which is a prominent advantage compared to other air jet mills, such as spiral mills (Mohs scale hardness of up to 3.5) (Clement and Purutyan 2002).

Additionally, impinging jet mills feature a separate classifier, e.g., rotating wheel, preventing unmilled solids from exiting the milling chamber until particles have reached a certain particle-size threshold (Fig. 4.4.). In the case of a rotating wheel classifier, the particle-size depends on the rotation speed of the wheel and the velocity of the gas exiting the mill (Godet-Morand et al. 2002; de Vegt et al. 2009). Varying the classifier speed is the normal technique used to control the particle-size distribution of the milled material; however, parameters such as grinding gas pressure and total gas flow rate can be modified to achieve the desired particle-size distribution and processing times. Changing nozzle diameter is the most common approach for control of these variables. It is important to note that when the parameters described here are fixed, the solids' feed rate does not normally affect the particle-size distribution, but it does affect the residence time and processing times.

Results will vary depending on the conditions used in the equipment and the properties of the solid (Rasenack and Müller 2004). However, for typical working pressures between 3 and 10 bar, particle sizes are usually tightly distributed due to the classifier and normally range between 1 and 10 μm . Typical surface areas achieved range from 2 to 5 m^2/g and are strictly dependent on the API hardness and friability (Fisher 2006).

One of the main limitations of this type of mill is the potential for buildup of compressed product in the mill or classifier due to the particle-wall and particle-classifier collisions. Accumulation of product in either of these compartments will change the geometry of the mill and will alter the performance and reproducibility of the equipment. In general, buildup at the exit of the mill or in the classifier will increase the particle-size over time owing to a reduced performance of the classification system. The material accumulated in the mill can become compressed or discolored or may change into an amorphous form, all of which will affect the product quality if it enters the milled batch stream. Even if intermittent cleaning is introduced in the process to avoid these problems, the impact in the overall productivity could be important.

Nakach et al. (2004) studied the effect of the air pressure at the grinding nozzles, the solids' feed rate, and the speed of rotation of the turbo selector. In their studies, they found a dependency of the specific surface of the product with the air pressure (P) and the speed of rotation of the classifier (N) (Nakach et al. 2004). The equation below indicates the relationship between air pressure and the classifier rotational speed, with the forces present in a dry mill.

$$\frac{P}{N^2} \propto \frac{\text{drag force}}{\text{centrifugal force}}. \quad (4.5)$$

It was found that 1–10 kg/h solids' feed rate had little influence on the specific surface of the product (Fig. 4.5). That particle-size is mostly controlled by the classifier. Furthermore, by recycling particles back into the mill, there is an increase in the mill holdup. The online sizing system evidenced that D_{50} and D_{90} varied considerably during operation, but D_{10} was more stable (Nakach et al. 2004).

Fig. 4.5 Specific surface created as a function of the factor P/N^2 for the fluidized air jet mill. From Nakach et al. (2004)

4.3.1.2 Spiral Jet “Pancake” Mill

Spiral jet or pancake mills have jets of air tangentially located around the center of the equipment in order to create a vortex of air. Particle-size reduction is a result of particle–particle and particle–wall collisions upon feeding of solids into the air stream (Fig. 4.6). Normally, gas velocities are such that a sonic flow is achieved and only particles that reach a predetermined particle-size will be able to leave the vortex through the exit. This internal orientation is advantageous due to the classification that naturally occurs in the system. Due to centrifugal forces, larger particles tend to remain near the perimeter of the milling chamber until the particle-size is reduced and they are light enough to travel to the center of the mill due to centripetal forces.

Particle-size reduction will depend on two main variables, namely the equipment and the solid to be milled. Geometric parameters of the equipment such as shape and diameter of the grinding chamber and shape/type, number, and angle of grinding nozzles will determine the performance of the milling process. Additionally, operating variables such as grinding jet air pressure, total gas flow rate, and solids’ feed rate play a role in the final particle-size distribution achieved (Friedrich 2001; Hoyer et al. 2008; Midoux et al. 1999; Schlocker et al. 2006).

Geometry Dependence

Midoux et al. (1999) have described the relationship between the volumetric flow rate V_n , the solid feed rate Q , and the diameter of the mill chamber D as follows:

$$V \propto D^2. \quad (4.6)$$

Moreover, the volumetric flow rate and the feed rate can be correlated Ito (1987):

Fig. 4.6 Above: scheme of a spiral jet “pancake” mill (Midoux et al. 1999). Below: scheme of a spiral jet mill with an additional classifier online (New Food Pharma Systems Spiral Jet Mill: Introduction 2010)

Fig. 4.7 The (1) abrupt nozzle and (2) Laval-shaped nozzle. In the scheme, the flow is from *left to right* (Albus 1964)

$$Q \propto V_n^{1.4 \pm 0.1}. \tag{4.7}$$

Finally, by combining the above two relationships a third relationship can be defined in terms of the solids’ feed rate and the mill chamber diameter:

$$Q \propto D^{2.8 \pm 0.2}. \tag{4.8}$$

According to a survey using the manufacturers’ product information, the above-derived relationship obtained is in accordance with what had been described before,

namely Q is proportional to $D^{2.3\pm 0.3}$, as well as to Smit's work on waxes describing a Q proportional to $D^{2.5\pm 0.2}$ (Smit 1986). Furthermore, the exponent seems to depend on the properties of the material being ground (Midoux et al. 1999).

Nozzle Dependence

The most common nozzle geometry is the abrupt type, providing sonic velocity at the inlet with an exit pressure of about 50% of the initial fluid pressure (Fig. 4.7). A suction that entraps particles from the mill is created after the final expansion occurs beyond the nozzle inlet. This phenomenon circulates the gas and induces particle–particle collisions. In the Laval-shaped nozzle, air expansion occurs at the divergent section. This leads to supersonic velocities, increasing the air jet action and the velocity of the circulating gas, therefore producing greater particle–particle collisions and thus increasing the production rate and reducing the average particle-size (Midoux et al. 1999).

Additionally, regardless of the type of nozzle, the number of nozzles is an important factor to consider in the performance of a jet mill. The influence of three different configurations, 3, 6, and 12 nozzles, while maintaining the total section of the nozzles and varying the solid's feed rates, has been studied (Skelton et al. 1980). It was found that a greater number of nozzles created a more regular pitch circle; furthermore, thinner jet nozzles led to minor perturbations of the spiral flow in the chamber. Accordingly, the design including 12 nozzles exhibited the best grinding ratio. Moreover, increasing the feed rates was also found to improve the grinding ratio.

The angle at which the nozzles are oriented toward the inner chamber of mill can be modulated, and their optimal values have been reported in the literature. If the angle is measured with respect to the tangent, Smit's optimum value was equal to 58° (Smit 1986) and Skelton's was between 52° and 60° (Skelton et al. 1980). Nonetheless, other operating angles ranging from 63° to 67° have been described in the literature (Midoux et al. 1999).

Working Conditions

In addition to the geometry of the chamber and the nozzles, operating variables can be controlled to obtain different outcomes. One of these variables is grinding pressure, which controls the gas mass flow rate input. As described by Midoux et al. (1999), if one assumes that the nozzles are isentropic, the initial grinding pressure P and the pressure at the nozzle throat P_t are related according to (4.9):

$$\frac{P}{P_t} = \left(1 + \frac{k-1}{2} M_t^2 \right)^{\frac{k}{k-1}} \quad (4.9)$$

where M_t is the Mach number at the throat and k is the ratio of specific heats of the gas. With this, a critical grinding pressure P_c can be defined as follows in (4.10):

$$\frac{P_c}{P_t} = \left(\frac{k+1}{2} \right)^{\frac{k}{k-1}}. \quad (4.10)$$

This critical grinding pressure is equivalent to the minimum pressure that yields a sonic flow at the nozzle inlet. Above this value, the gas mass flow rate M_g can be expressed by (4.11):

$$M_g = PA \sqrt{\frac{M_w k}{RT} \left(\frac{2}{k+1} \right)^{\frac{k+1}{k-1}}}. \quad (4.11)$$

As can be derived from the (4.11), M_g is directly proportional to the grinding pressure P , the throat section A , and the molecular weight M_w of the fluid employed for grinding. The gas kinetic energy (\dot{E}_k) can be defined by (4.12):

$$E_k = \frac{1}{2} M_g v_g^2. \quad (4.12)$$

The concept of specific energy consumption (E_{sp}) has been used in the literature (Kaiser and Nied 1980; Schurr and Zhao 1994; Stairmand 1975) to correlate solid's feed rate and grinding pressure, which is directly correlated to the gas kinetic energy (defined above). According to Schurr and Zhao, this is calculated by (4.13) (Schurr and Zhao 1994):

$$E_{sp} = \frac{\dot{E}_k}{Q}. \quad (4.13)$$

With this value, different mills and different working conditions can be compared on the same system. In a spiral jet mill, the specific surface area (SSA) of the product is related to E_{sp} by a power function as follows in (4.14):

$$SSA \propto E_{sp}^x. \quad (4.14)$$

In their studies, Midoux et al. (1999) corroborated that the SSA was dependent on the grinding pressure and the solid's feed rate and could compare different systems. It was found that for the same material, the specific energy required to obtain a certain grinding ratio diminishes with the mill diameter. Additionally, a different material exhibited a clear E_{sp} transition around 400 kJ/kg. Below this value, SSA was proportional to E_{sp} with an exponent of 1.1; however, above the critical value of E_{sp} , the exponent decreases sharply as can be seen in Fig. 4.8.

In general, high grinding jet pressures result in smaller particle-size distributions. The solids' feed rate is strictly related to the solids' concentration in the mill and thus, higher feed rates will produce coarser particle sizes, while lower feed rates will result in smaller particles (Midoux et al. 1999). It has been found in the literature that an optimal feed rate can be achieved to yield the tightest particle-size dis-

Fig. 4.8 Correlation between E_{sp} versus ΔSSA

tributions at a set average particle-size (Midoux et al. 1999). These mills are suitable for rather soft materials with a Mohs scale hardness of up to 3.5 (Chamayou and Dodds 2007). Nonetheless, they are widely used in the industry due to two main advantages: there are no moving parts in the equipment, and the Joule–Thomson effect produced by the expansion of the gas passing through the nozzles results in cooling in the mill. This effect can control or decrease the temperature of any local temperature increases caused by friction (Fisher 2006).

4.3.1.3 Pin Mill

A pin mill is a mechanical energy impact mill. Of all dry mills used without a classifier, the pin mill achieves the smallest average particle sizes (Nied 2007). In the pin mill, rotating elements in the equipment allow for particle–particle and particle–mill collisions. A limited internal classification can be achieved if appropriate elements are selected as milling tools.

The milling equipment comprises two disks fitted with overlapping pins as depicted on Fig. 4.9. The pin mill is a type of rotor–stator mill; therefore, one of the disks is the stator and the other one rotates with a high peripheral speed of up to 150 m/s. An additional modification of the design consists of having two counter-rotating pin disks, which allow for peripheral speed of up to 250 m/s (Nied 2007). The solids are fed at a controlled rate into the center of the stator by means of a screw. They are crushed through intermeshing rings of the rotor and stator pins and the milled product leaves by centrifugal forces to the periphery to be collected or further processed.

Besides the properties of the solid, the final average particle-size of the milled product is determined mainly by rotor tip speed, solids' feed rate, and gas flow rate through the mill. By optimizing the process, small average particle sizes can be achieved when rotor tip speed is maximized, and both solids' feed rate and airflow rate are minimized (F. Muller and Polke 1999). This is illustrated in Fig. 4.10, where it can be seen that D_{90} decreases with increasing tip speed but increases when

Fig. 4.9 Schematic representation of a pin mill in which the rotor and the stator are pin disks (Nied 2007)

Fig. 4.10 Influence of tip speed and solids feed rate on reducing the particle-size, expressed as D_{90} in μm (Muller et al. 1999)

the solids' feed rate is increased. The rotor tip speed is an adequate way to achieve comparable results for scaling-up purposes (Fisher 2006).

An investigation by Nakach et al. (2004) studied the effect of variables such as the tip speed (or rotation speed) and the solids' feed rate. Additionally, the effect of the type of pin mill was studied in terms of manufacturer and whether the equipment was a single- or double-rotor pin mill (Nakach et al. 2004). As can be seen in Fig. 4.11 the SSA increases linearly with the square of the peripheral speed up to 150 m/s for the different sizes of mills studied (expressed as diameter in mm).

Fig. 4.11 Specific surface as a function of the square of the peripheral speed for three different sizes (expressed as diameter in mm) and types of mills (Nakach et al. 2004)

Fig. 4.12 Relation between the specific surface area and the factor P/N^2 in a pin mill with a dynamic selector (Nakach et al. 2004)

Further studies with a pin mill attached to a dynamic selector found that the product quality was essentially dependent on the performance of the selector Fig. 4.12. The selector had 12 blades and rotated up to 5,000 rpm. After the solid was milled in the pin mill, only fine particles are able to enter the selector due to the centrifugal force repulsing the pass of coarser particles, which are brought back to the milling chamber until a suitable particle-size is achieved. This mode of operation is similar to what has been described for fluidized air jet mills, and SSA is dependent on the air pressure P and the speed of rotation of the selector N (see (4.5)).

One of the main concerns with the use of pin mills (and any impact mill) is the generation of heat due to friction (am Ende and Rose 2006). This is of particular importance for thermally labile drugs and materials, with relatively low phase-transition temperatures (<80–100°C). Inadequate training and subsequent poor operation of the mill can result in increasing the temperature beyond normal ranges. For example, if the feed rate is higher than the discharge rate the mill can be “choke fed,” such that there is an accumulation of solids in the mill chamber, resulting in heat buildup. As stated above, with other types of milling equipment, due to the high temperatures generated in the milling chamber phase transitions may occur and amorphous material could be formed during the operation (Fisher 2006). This phenomenon has direct consequences for stability of the product and can affect the performance reproducibility from batch to batch.

Depending on the properties of the solid, the average particle sizes and the surface areas obtained in impact mills can range from 5 to 20 μm and from 1 to 2 m^2/g , respectively (Fisher 2006).

4.3.1.4 Environmental Limitations of Dry Milling

Even though the particle-size reduction mechanisms involved in the previously described mills may differ, in general, during the process of dry milling a large amount of small size particles are produced, also known as fines, and they need to be minimized in order to prevent operator exposure and reduce the environmental impact. If recovery of the fines is needed in order to combine the fraction with the batch bulk material, a pharmaceutical grade dust collector could be used (Boundy et al. 2006).

Additionally, most milled APIs produce a potentially explosive dust (Fisher 2006; Hamelmann and Schmidt 2003). Certified laboratories perform studies of minimum ignition energy (MIE), which is the least amount of energy that is required to ignite a dust sample. For the purpose of a safe estimation, the concentration of dust used is that which will allow for the minimum energy input for ignition. An MIE lower than 20 mJ indicates that low energy sources can potentially ignite the dust sample (Stevenson 2001). For example, static electricity discharge could be one of the low energy sources that could potentially create the explosion (Eckhoff 2003). In cases like these, a thorough and careful evaluation of the processing environment is needed in order to prevent any conditions that could yield sufficient energy to create a dust explosion. In data from Merck and Co., Inc., regarding MIE values (in mJ) for dust samples (Fisher 2006). It has been found that even though the majority of the samples do not impose a risk for explosion, 20% of the samples have an MIE of 10 mJ or less, requiring special handling conditions to prevent ignition.

There are three main strategies used for dust explosion control, namely preventing the development of explosive mixtures (dust clouds), preventing the occurrence of ignition sources, and strategies for mitigation (Table 4.1).

Table 4.1 Means of preventing and mitigating dust explosions (Eckhoff 2003)

| Prevention | | |
|--|---|--|
| Preventing ignition sources | Preventing explosive dust clouds | Mitigation |
| Smoldering combustion in dust, dust flames | Inerting by N ₂ , CO ₂ , and rare gases | Partial inerting by inert gas |
| Other types of open flames | Intrinsic inerting | Isolation (sectioning) |
| Hot surfaces | Inerting by adding inert dust | Venting |
| Electric sparks and arcs, electrostatic discharge | Dust concentration outside explosive range | Pressure-resistant construction |
| Heat from mechanical impact (metal sparks and hot spots) | | Automatic suppression Good housekeeping (dust removal and cleaning) |

A common source of ignition in the industry is the presence of hot surfaces. Contrary to what has been accepted in the past, minimum hot-surface ignition temperatures of dust clouds vary significantly when scaling up. To better estimate the value when scaling up, both the magnitude and the geometry of the hot surface in relation to the dust cloud should be considered (Eckhoff 2005).

Other common sources of ignition are the electric and electrostatic discharges. Switches, failures in electric circuits, and common discharge of static electricity are some examples of these sources. Parameters from the dust cloud that can contribute to the ignition are the particle-size/shape distributions, dust moisture content, dust concentration, and the dynamic state of the dust cloud with respect with the spark gap (Eckhoff 1994).

To prevent explosive dust clouds, an inert gas, such as nitrogen or carbon dioxide, can be mixed in the dust to a level where the dust can no longer ignite in the operating conditions. In contrast with what has been previously reported in the literature (Wilén et al. 1999), it has been found that the limiting oxygen concentration (LOC) increases with an increase in the initial pressure (in the range of 5–18 bar) (Schwenzfeuer et al. 2001). It has been reported that the LOC for ignition of dust clouds by electrostatic discharges or metal sparks was significantly higher than that determined in standard tests by using a very strong pyrotechnical ignition source (Schwenzfeuer et al. 2001). Nonetheless, decreasing the oxygen in the process can impose the risk of suffocation on the operator. To overcome this limitation, it has been shown that adding a small volume % of CO₂ to the inert gas mixture can significantly reduce the critical oxygen threshold for suffocation (Eckhoff 2005).

Other operations, such as charging powders into other units, packaging solids from a milling system, or cleaning equipment after operation, can create a dust cloud that could lead to explosive conditions. Therefore, attention to housekeeping and the procedures used for these other operations also has importance (Fisher 2006).

With an overall industry increase of very potent APIs, personnel protection has become particularly important. By decreasing the particle-size and creating fines in the process, dry milling is an operation that increases the risk of exposure to personnel compared to wet-milling (Stein et al. 2010). This could eventually dictate the choice of milling equipment due to the increased cost of production of dry milling

and the protective equipment that personnel need to operate the mill. Wet-milling in cases of a very potent API can be a more cost-effective choice.

4.3.2 *Wet-Milling*

Wet-milling, also known as slurry milling, is a particle-size reduction process in which the solid particles are suspended in a liquid medium. As such, wet-milling has a number of advantages over dry-milling, thermal control over the process being one of the most prominent. Due to the thermal control, heat-labile materials can be processed through this technique simply by the thermal properties of the liquid in the slurry. If additional cooling is needed, the liquid can be precooled or cooled during the process to control the temperature. As stated above, this could prevent chemical decomposition, solid phase transitions, or melting of the material being milled (Merisko-Liversidge et al. 2003).

A common concern in submicron particle-size reduction techniques is the particle-size change due to dissolution of fine particles and/or growth on larger particles (Merisko-Liversidge and Liversidge 2008). The latter phenomenon, known as Ostwald ripening, can occur with any material and is accentuated when the solubility is a function highly dependent with temperature. This can be of particular relevance upon scaling up because the milling chamber surface area to batch volume ratio decreases, which ultimately influences the heat transfer in the process (Fisher 2006). Additionally, due to significant heating/cooling cycles that could occur during wet-milling, an annealing effect could potentially be induced in the solids (Trasi et al. 2010).

The system of mechanical sealing of wet-milling equipment needs to be controlled due to two main issues that can arise: contamination of the batch and seal lifetime. For the sealing system to operate, a seal fluid is normally used for lubrication and cooling purposes. Therefore, there is always the potential of contamination of the batch with the seal fluid; thus the fluid needs to be compatible with the solvent and API used in the milling process (Fisher 2006). Additionally, the sealing system should be thoroughly cleaned to extend the seal lifetime and decrease the chances of batch contamination.

The particle-size achieved in a batch will normally depend on the type of wet-milling equipment that is used. However, in general particle-size will be a function of the residence time of the slurry in the mill (Stenger et al. 2005). This residence time can be controlled by operating the system in either single-pass or recycling mode. In either modality, it is important to determine and control the slurry flow rate when considering the scale-up process. Furthermore, depending on the mill, it should take a predetermined number of passes to achieve a steady particle-size distribution.

In the pharmaceutical field, there are two common types of wet mills: rotor–stator and media (bead) mills (Fig. 4.13). The latter is widely used due to its capacity to produce particle sizes in the nanoscale range but at the cost of longer milling times

Fig. 4.13 Rotor–stator geometries: (a) simple Coette conical geometry (also known as colloid mill) and (b) toothed rotor–stator

(Kipp 2004). The rotor–stator mill is widely used in the field for emulsification and homogenization and can be used in the wet-milling of APIs, achieving particle sizes in the 20–30 μm range (Atiemo-Obeng and Calabrese 2004; Lee et al. 2004).

4.3.2.1 Rotor–Stator Wet Milling

Rotor–stator milling equipment are also referred to as high-shear devices due to the shear rates generated during the rotation of the mixing element (rotor), which has a close proximity with the static element. Probe rotor–stator mills are useful for small-scale development and are normally used as batch process-type vessels. Even though data from this setup can be used as a reference for scaling-up purposes, the average particle sizes might not be comparable upon increasing the batch size. At the scale of tens of grams or more, a flow-through unit is the preferable choice, as these systems allow the slurry to pass through the high-shear patterns in the mill repeatedly, further decreasing particle-size and narrowing the particle-size distribution (Nied 2007).

With toothed probe rotor–stator mills (Fig. 4.14), the mechanism of particle-size reduction is believed to occur as a combination of high shear and collision of particles with each other and the equipment walls (Atiemo-Obeng and Calabrese 2004). As a consequence, parameters that control the high shear of the equipment ultimately control the performance of the mill in terms of particle-size distribution. Tip speed (rotation rate of rotor \times rotor circumference), shear rate (tip speed/distance between rotor and stator), and shear frequency (rotation rate \times number of slots on rotor \times number of slots in stator) are the typical design parameters that can be controlled in the development of a rotor–stator mill (Lee et al. 2004). For scaling-up purposes in equipment that has a fixed rotor–stator design to preserve rotor tip speed, scaling to a larger design results in milled particle sizes that are comparable to those obtained in small-scale batches.

Fig. 4.14 Different stirrer and grinding chamber geometries (Kwade 1999)

As with other milling equipment, the solids' concentration in the slurry will typically be directly related to the milling efficiency and cycle time. In general, increasing the total solids' content will increase the milling rate. Nonetheless, there is a limit to the slurry concentration, in terms of limiting the flow of the media and potentially plugging the milling equipment (Atiemo-Obeng and Calabrese 2004).

In general, the average particle sizes obtained using a rotor–stator mill can be of a few microns, with a D_{95} normally not being larger than 40–50 μm (Fisher 2006). The hardness of the milled material dictates the cycle time when the goal is to obtain narrow particle-size distribution. A common phenomenon observed with hard, block-like materials is the potential for multimodal distributions (Lee et al. 2004). With these materials, breakage is believed to occur mainly at corners and edges, which

Fig. 4.15 Bead mill DISPERMAT (use register mark symbol) SL for mill base amounts of 50 mL 50 L. Schematic representation of the laboratory mill Dispermat SL (Modified from Schilde, Nolte, Arlt, & Kwade, 2010)

translates into “chipping” of the hard material resulting in a high population of fines and larger particles yielding bi or multimodal particle-size distributions.

4.3.2.2 Media (Bead) Wet-Milling

This type of mill operates by mechanically moving media (beads) together with the material (normally the API) in a liquid. This can be done either by means of a stirrer or by agitating the container itself. The beads can be made of various materials; however, they are normally glass spheres, ceramics, metal, or plastic. The bead densities can range between 2,500 and 7,800 kg/m³, with sizes between 0.1 and >10 mm (Kwade and Schwedes 2007). Closed stirred media mills can be arranged either vertically or horizontally and are normally equipped with a thermal jacket for cooling purposes. According to the chamber and stirrer geometry, three types of mills can be distinguished, namely a disk stirrer, a medial mill with pin-counter-pin stirrer, and an annular gap geometry (Fig. 4.15).

The efficiency of the mill is related to a combination of many variables, such as media speed, amount of loaded media, slurry concentration, and milling time (Blecher and Schwedes 1996; Blecher et al. 1996; Kwade 2003 and Schilde et al. 2010). Additionally, material properties and the overall mill design are also factors contributing to milling performance. Table. 4.5.

The specific characteristics of the milling media will greatly influence the performance of the milling process. Among different geometries of the milling media, it has been found that the spherical geometry is the most effective shape (Fisher 2006). Manufacturers offer different beads with diameter ranging from 0.2 to 130 mm; however, beads 6 mm and smaller are normally used. Beads can also be obtained in various materials such as (in order of decreasing density): various grades of steel, ZrO_2 , $ZrSiO_4$, Al_2O_3 , SiO_2 , annealed glass, polytetrafluoroethylene (PTFE), and hard polystyrene derivatives (Keck and Muller 2006).

In direct comparison with a rotor–stator wet mill, media milling equipment can yield much smaller average particle sizes for the same material. Average particle sizes can range from the 1–2 μm to the nanoscale range, with adequate distribution of particle sizes when proprietary media or additives in the slurry have been used (Bruno et al. 1996; Liversidge et al. 1992). With such a pronounced particle-size decrease, surface areas in 1–2 μm size batches can be 4–5 m^2/g and higher. Furthermore, nanoparticles obtained by this milling method can have a surface area of 10 m^2/g or more (Fisher 2006; Muller et al. 2001).

The fundamental processes that control particle-size reduction in this type of equipment are the number of stress events and the stress intensity. In general, the average number of stress events for each particle, SN , is determined by the number of media contacts, N_c , the probability that a particle is caught and sufficiently stressed at a media contact, P_s , and the number of product particles inside the mill, N_p (Kwade 1999):

$$SN = \frac{N_c P_s}{N_p}. \quad (4.15)$$

As stated above, the factors determining the number of stress events and stress intensity are dependent on the design and residence time in the mill. Scaling up can be complicated by the differences in relative contributions of number of stress events and stress intensity and if power per unit volume for larger mills decreases (Bell 2005). Nonetheless, it has been previously reported that comparable particle sizes, around <150 nm, can be achieved upon scaling up mill sizes from the same manufacturer. Key parameters such as bead loading, agitator tip speed, and linear velocity of the slurry, were kept constant during scaling up and yielded acceptable average particle sizes (Shelukar et al. 2003).

One issue concerning the operation of this type of mill at high throughput rates is hydraulic packing. This phenomenon is related to the milling media being concentrated at the mill exit (packing), instead of remaining in the milling chamber during the operating cycle, which translates in reduced milling efficiency. Hydraulic packing can result in an increase in power consumption, together with an additional

heat input to the sample batch (Shelukar et al. 2003). The flow rate that triggers hydraulic packing has been found to be related to increasing agitator tip speed, reduced bead loading, as well as the sample batch viscosity.

Another limitation found in milling processes performed in media mills is the potential for shedding of the media and components into the batch. It has been found that the use of glass beads yielded glass microparticles in the final product (Buchmann et al. 1996; Kipp 2004). Since no further purification steps are normally considered after milling of APIs, it is important during developmental stages of the process to assess the amount of objectionable substances in the batch. For API manufacture, these levels are normally in the parts per million range (Fisher 2006); however, they can be as high as 70 ppm, imposing development limitations in the process (Keck and Muller 2006). To overcome or limit the extent of these materials in the final batch, an additional premilling step that decreases the coarse particle-size of the raw product can be performed to reduce the residence time of the batch in the wet mill, therefore reducing total shedding (Shelukar et al. 2003).

The wet-milling technology has been further developed by G. Liversidge and coworkers and turned into the high-energy media milling NanoCrystal technology by Elan for obtaining nanoscale nanocrystalline particle distributions of API (Liversidge et al. 1992). The nanoparticle dispersions obtained by this technology consist of the API and a surface stabilizer to avoid aggregation and subsequent particle growth (Merisko-Liversidge and Liversidge 2008). To minimize the shedding of materials, the technology makes use of highly cross-linked polystyrene beads; however, the extent of erosion is dependent on a combination of the bead material and the physical characteristics of the drug (i.e., hardness) and the residence time (Keck and Muller 2006). The grinding process developed by Liversidge et al. has a limitation upon scaling up due to the heavy weight that it would impose, increasing the size of the mill.

Particles obtained by media milling that are in the range of a few microns to the nanoscale are generally required to be stabilized using surface active agents or surfactants to prevent particle growth (Lee et al. 2005; Van Eerdenbrugh et al. 2008). The process normally begins with the formation of a macrosuspension in which the surfactant is added, followed by the wet-milling process itself. The surfactant to be used will be determined by a number of factors including the properties of the solid to be suspended (affinity of the solid with the surfactant), physical mechanism of action (electrostatic vs. steric stabilization), and route of administration of the nanosuspension (Berglund et al. 2003; Lee et al. 2005). Steric stabilization can be a more effective choice when there is a chance for poor gastrointestinal or systemic stability due to excess electrolytes. Ionic surfactants can also provide sufficient stabilization by reducing the zeta potential, thus preventing particle aggregation. In many cases, the final choice is a combination of both steric and electrostatic stabilization using a combination of surfactants. There is a wide variety of surfactants that can be used for the development of nanosuspensions meant for oral administration; however, for the parenteral route the choices are limited. Lecithins, Poloxamer 188, Tween 80, low-molecular weight polyvinylpyrrolidone (PVP), and sodium glycocholate

Fig. 4.16 Diagram of the ultra cryomilling apparatus in liquid nitrogen developed by Niwa et al. The beads, disks, shaft, and inner wall of the vessel were made of zirconia (Niwa et al. 2010)

(combined with lecithins) are surfactants that have been accepted for injection (Muller et al. 2006).

The number of different media mills available in the market range from laboratory-scale to industrial-scale volumes. Upon scaling up, there is need for equipment that can handle large volumes (and weights) of media and product. Since enlarging the whole milling unit would require a large amount of milling media, an external suspension container has been devised for operating mills with large-scale batches (Fig. 4.16). With this arrangement, an additional container feeds a suspension to the milling system in more discrete quantities, allowing a smaller mill to decrease the particle-size of large quantities of feed. The downside of this strategy is the increase in milling times (Muller et al. 2006).

4.3.2.3 Cryogenic Milling

The term cryomilling has been used in the literature to describe two different processes involving cryogenic conditions. The first is a grinding technique in which the solids are milled in a slurry formed with a cryogenic milling media. The other configuration consists of using a cryogenic liquid to decrease the temperature of the grinding chamber and mill the solids as in dry milling. Nonetheless, both operations rely on a cryogenic substrate to control the temperature of the process while decreasing by attrition the average particle-size (Witkin and Lavernia 2006). The direct and obvious advantage of the process is the suitability for thermally labile compounds; however, the removal of the cryogenic liquid upon finishing the milling process may impose certain limitations (Fisher 2006).

Fig. 4.17 Basic homogenization principles: piston gap (*left*) and jet-stream arrangement (*right*). In the piston gap homogenizer the macrosuspension is forced to pass through a small gap (few microns), and particle breakage is due to shear forces, cavitation, and impaction. In jet-stream homogenizers the collision of two high-velocity streams leads to particle breakage mainly by impact forces. (Adapted from R. H. Muller et al., 2006)

A recent investigation by Niwa et al. (2010) coined the term “ultra cryomilling” and was used for media milling that explicitly uses liquid nitrogen as dispersant (Fig. 4.17). Liquid nitrogen was used as the cryogenic liquid due to its poor solubilizing potency. Furthermore, the low surface tension (8.85 mN/m at -196°C) and viscosity (0.158 mPa at -196°C) exhibited by liquid nitrogen might prevent secondary coaggregation and undesired particle growth. Additionally, materials under very low temperatures (-196°C for liquid nitrogen) become more brittle and can be milled more efficiently (Reed 2007).

In the investigation by Niwa, after optimizing for size and amount of zirconia beads and agitation speed, crystalline nanoparticles were obtained (Niwa et al. 2010). The authors found that, by increasing the agitation speed of the shaft from 550 to 1,600 rpm, the average particle-size could be decreased. This was attributed to a higher kinetic energy imparted on the beads, thus creating high-impact collisions between particles and beads. The bead size in the 0.1–1 mm diameter range was found not to impact the performance of the milling process, both achieving similar particle-size distributions. For the purpose of comparing the performance of the novel cryomilling technique, the authors used 1 mm beads. Powders processed by the ultra cryomilling technique were comprised of 21.5% submicron particles, while powders processed by jet milling only achieved 9.07% of submicron particles (Niwa et al. 2010). The process was shown to work with a wide variety of drugs in terms of their physicochemical characteristics such as heat sensitivity and water solubility. It was further demonstrated that the crystalline structure found in the bulk solid remained after processing. One inherent limitation of the process though is the aggregation of particles upon liquid nitrogen evaporation. To account for this, the authors proposed an additional formulation design mainly focused on adding a surfactant to increase the wettability of the particles.

Fig. 4.18 Flow chart of the particle size reduction process in the Microfluidizer (Adapted from Singh and Naini 2006)

4.4 High-Pressure Homogenization Techniques

Homogenization is a process by which the particle-size distribution of a suspension or an emulsion is narrowed or “homogenized”, thus decreasing the polydispersity of the sample. Particle breakage is achieved by a combination of high shear, turbulence, impact, as well as cavitation in the homogenizer. The type of homogenizer used determines which of these mechanisms will be more important for particle-size reduction together with the physical properties of the bulk powder.

4.4.1 Piston-Gap Homogenizers

Piston-gap homogenizers work with pure water as dispersant and rely on cavitation as the driving force for particle diminution. In these homogenizers, the suspension (or sometimes a coarse emulsion) passes through a very thin gap at very high velocities. Before entering the gap, the suspension is contained in a cylinder with a relatively large diameter compared to the width of the gap (Fig. 4.18). This tremendous decrease in diameter leads to an immense drop in the static pressure of the liquid. The resulting static pressure is below the vapor pressure of water, leading to boiling and the creation of gas bubbles that implode after leaving the gap, returning to normal pressure in the reservoir compartment of the homogenizer. This first technology, known as DissoCubes, considered this phenomenon, cavitation, as a primary factor in particle breakage (Muller et al. 1999).

Particle-size decrease is controlled by several factors: homogenization pressure, number of homogenization cycles, and hardness of the drug and stabilizers (Keck and Muller 2006). In general, increasing the pressure will translate to a decrease in average particle-size; however, this relationship is not always linear. It has been found that up to a pressure of 4,000 bar there is a certain pressure above which particle-size diminution does not decrease any further (Fichera et al. 2004). The reason for this phenomenon appears to be that upon crystal breakage and particle-size reduction the imperfections in particles become reduced in number per particle, thus decreasing the chance for particle breakage. A decrease in average particle-size may also result from an increase in the number of homogenization cycles. In general, after five cycles, further increasing the number of cycles does not decrease the batch D_{50} (Keck and Muller 2006). Increasing the number of cycles to 15–20 does have an impact on the homogeneity of the sample and is reflected in a decrease of the batch D_{95} . As in other grinding techniques, softer material can be processed to achieve smaller average particle sizes when processing conditions are kept the same. Paclitaxel, a soft drug, has been reported in the 250 nm range after 10–20 homogenization cycles at 1,500 bar. A harder drug, azodicarbonamide, has been found to achieve particle sizes ranging from 500 to 800 nm, depending on the processing conditions (Keck and Muller 2006). Finally, the nature and concentration of the stabilizer (either surfactant or polymer) in the formulation, as opposed to emulsions, has been found to not affect the extent of particle-size diminution, although it does have an impact on aggregation in the long term (Muller et al. 1996).

4.4.2 *Microfluidizer*

The mechanism of particle-size reduction for this high-pressure homogenization technique is through the impaction of jet streams (Dearn 2000). As seen in Fig. 4.19, prehomogenized liquid is pumped through an interaction chamber where impaction occurs. The interaction chamber is composed of microchannels that split the liquid line in two. These two streams are then recombined at high velocities to produce forces of shear, impaction, and cavitation. These forces combine to cause particle breakage and size reduction. A detailed description of the operation and examples of the use of the microfluidizer can be found in US patent 4,553,254 (Cook and Lagace 1985).

A disadvantage of this technology is that the product obtained can have a rather large quantity of particles in the larger size range (Illig et al. 1996). Furthermore, a high number of passes have been described in patents, reaching sometimes even 75 passes and ultimately translating into long processing times. Additionally, the system is more compatible with soft drugs, enabling nanosuspensions to be achieved during processing (Keck and Muller 2006; Muller et al. 2006). Larger particles often result when harder drugs are processed by this method, reducing the extent to which solubility can be increased through mechanical size reduction.

4.5 Conclusion

The number of new drugs and drug candidates with poor aqueous solubility is on the rise and there is a need to overcome this limitation. Decreasing particle-size achieves an increase in surface area, saturation solubility, and a decrease in diffusional distance, all of which ultimately result in an increase in the extent and rate of dissolution for a given material. Strategies that rely on mechanical particle-size reduction, also known as the top-down approach, can be roughly classified into milling techniques and high-pressure homogenization techniques. Of all the strategies, wet-media milling, piston-gap homogenization, and microfluidization are the most popular techniques. These widely used approaches may yield particle-size distributions in the low micron to the nanoscale range. Various technologies have been patented using the top-down approach. Technologies such as NanoCrystal[®] by Elan and IDD-P[®] by SkyePharma are the only top-down technologies that yield particles in the nanoscale range and are currently used in marketed products. In addition to these successfully commercialized technologies, there are several other pipelines incorporating mechanical particle-size reduction using different techniques, demonstrating the growing acceptance of particle-size reduction as a means of improving drug water solubility.

Method Capsule 1

Particle-Size Reduction by Spiral Air Jet Milling

Based on the method reported by Schlocker et al. (2006).

Objective

- To obtain protein-loaded microparticles with adequate protein stability after processing. Horse-radish peroxidase was used as model protein and was co-precipitated with either carbomer or a poly(methacrylate) prior to grinding.

Equipment and Materials

- Carbopol 934P and Eudragit L 100–55 as polymer matrix.
- Horseradish peroxidase as protein model.
- Spiral jet mill (Hosokawa Alpine Aeroplex 50 AS) with a diameter and height of grinding chamber 50 and 4.5 mm respectively; standard blowing-out nozzle; number of nozzles 4; nozzle diameter 0.8 mm; nozzle pitch 50°; and equipped with a temperature sensor (Lutron, DH-802C, Ming Chuan, Taiwan).

Method

- After co-precipitation of the model protein and one of the model polymer matrices, 1 g of the powder was added in the chamber of the spiral air jet mill.
- Injector air pressure was 7.5 bar.
- Grinding air pressure (GAP) was either 2.5 or 4.5 bar and the powder was ground for 10 min.
- After milling, the material was collected from the grinding chamber and stored at –18°C.

Results

- After laser diffraction analysis, it was revealed the increasing the GAP in the mill decreased the microparticles' size.
- Using isopropanol as the nonsolvent in the co-precipitation of the protein and carbomer and increasing the GAP from 2.5 to 4.5 bar decreased D_{50} from 5.2 to 2.7 μm . By using petroleum ether as the nonsolvent in the co-precipitation of the protein and poly(methacrylate) and increasing the GAP from 2.5 to 4.5, the D_{50} was decreased from 4.5 to 2.8 μm .
- A GAP of 4.5 bar in the case of the poly(methacrylate) reduced protein stability (measured as activity after processing) almost completely, while at 2.5 bar 58% activity remained. In the case of carbomer, increasing GAP from 2.5 to 4.5 bar decreased the remaining activity from 75 to 35%.
- The spiral air jet mill was found to be an effective process for the manufacture of protein-loaded microparticles with adequate protein stability after processing.

Method Capsule 2**Particle-Size Reduction by Media Milling**

Based on the method reported by Liversidge et al. (1992).

Objective

- To obtain a suspension of PVP surface-modified crystalline danazol nanoparticles to improve bioavailability.

Equipment and Materials

- Wet-media mill with a 600 mL cylindrical vessel (inner diameter 7.6 cm).
- 200 mL of zirconia grinding media (0.85–1.18 mm diameter).
- Micronized danazol (mean particle-size 10 μm).
- PVP K-15.

Method

- Zirconia grinding media was added to the vessel of the mill.
- Micronized danazol and PVP were added to the mill and water was used as a dispersing agent to an adequate volume.
- The vessel was rotated horizontally around its axis at 57% of the critical speed.
- After 5 days of milling, the slurry was separated from the grinding media by sieving.

Results

- A sedimentation field flow fractionator was used for sizing and, after processing, the number average weight was 84.9 nm and the weight average weight was 169.1 nm.

- Particle-size of the batch ranged from 26 to 340 nm.
- X-ray diffraction demonstrated that the crystalline structure of danazol remained unchanged after the process.
- Dispersions of unmilled danazol and the nanoparticulate slurry were dosed in beagles. The relative bioavailability of danazol from the nanoparticulate dispersion was 15.9-fold higher than from the danazol suspension containing microparticles (10 μm).

Method Capsule 3

Particle-Size Reduction by Ultra Cryomilling

Based on the method reported by Niwa et al. (2010).

Objective

- To obtain nanocrystals by a one-step milling process for drugs with a wide variety of physical properties, such as heat sensitivity, oxidizability, or water solubility.

Equipment and Reagents

- Liquid nitrogen
- Phenytoin
- Batch-type wet mill with a 400-mL capacity vessel
- Zirconia rotation shaft, disks, and beads
- Sieve No. 60 (0.25 mm)

Method

- Similar to a typical wet-milling process, the drug is suspended in liquid nitrogen and the suspension of drug and milling beads is vigorously agitated.
- Precool the parts of the mill (vessel, shaft, disks, and beads) with liquid nitrogen.
- Fill the milling vessel with 550 g of zirconia beads 1 mm diameter (approximately 150 mL).
- Suspend 15 g of phenytoin in liquid nitrogen and fill the milling chamber to 360 mL.
- Start and maintain a controlled agitation at 1,600 rpm for 30 min, and pour additional liquid nitrogen to account for loss due to volatilization.
- Pass the slurry through a sieve to separate the powder from the beads.
- Collect the milled powder after all the liquid nitrogen evaporates.

Results

- After laser diffraction analysis, the particle-size profile revealed a D_{10} , D_{50} , and D_{90} of 0.62, 1.84, and 5.27 μm , respectively, with a 27.5% of submicron particles per batch.

- X-ray powder diffraction patterns and DSC curves indicated that the crystalline structure of particles before milling remained after the process.
- The crystalline habit of the particles remained the same as the initial.
- Milled particles tend to agglomerate; they may require a wetting agent for dispersion.

Method Capsule 4

Particle-Size Reduction by Piston-Gap High-Pressure Homogenization

Based on the method reported by Grau et al. (2000).

Objective

- To reproducibly obtain a 1% potency nanosuspension of 4-[N-(2-hydroxy-2-methyl-propyl)-ethanolamino]-2,7-bis(cis-2,6-dimethylmorpholin-4-yl)-6-phenyl-pteridine in water using a piston-gap high-pressure homogenizer.

Equipment and Materials

- Micron Lab 40 (APV Deutschland GmbH, Germany), 40 mL capacity high-pressure homogenizer.
- 4-[N-(2-hydroxy-2-methyl-propyl)-ethanolamino]-2,7-bis(cis-2,6-dimethylmorpholin-4-yl)-6-phenyl-pteridine.
- Tween 80.
- Glycerol.

Method

- The drug is suspended in an aqueous solution containing the surfactants.
- At room temperature, the suspension is homogenized using a variable pressure profile.
- Two cycles are performed at 150 bar.
- Two more cycles are performed at 500 bar.
- Finally, 10 cycles are performed at 1,500 bar.
- If needed, at the end of any cycle draw a slurry sample to determine particle-size.
- At the end of the particle-size reduction process, collect the nanosuspension from the high-pressure homogenizer.

Results

- After the whole homogenization cycle (14 cycles), photon correlation spectroscopy revealed a mean diameter of 502 nm and a polydispersity index of 0.390.
- Laser diffraction data revealed D_{10} , D_{50} , and D_{90} of 0.31, 0.95, and 2.20 μm , respectively.
- High reproducibility was found for the mean size in between batches and at each cycle number with the parameters utilized in the high-pressure homogenization process.

Chapter 5

Solubilized Formulations

Feng Zhang and James C. DiNunzio

Abstract Co-solvent based, polyethylene glycol (PEG)-based, and lipid-based solubilization techniques for the delivery of poorly soluble drugs are discussed in this chapter. The properties of excipients and the physicochemical principles are presented for formulating each type of the solubilized formulations. Co-solvents are commonly used in combination with surface active solubilizers to increase the solubilizing capacity and to improve the in vivo emulsification of self-emulsifying formulations. In PEG-based delivery systems, drug is either dispersed as micronized crystalline particles (via the formation of eutectic mixtures) or present in its amorphous state. Improvement in absorption from PEG matrix is due to (1) fast dissolution rate of drug from the dosage forms and (2) higher transient solubility of the drug substance in gastrointestinal tract. The mechanisms of improved absorption from lipid-based solubilized formulations include (1) enhanced dissolution and solubilization in vivo; (2) prolongation of gastric residence time; (3) stimulation of lymphatic transport; and (4) reduced metabolism and efflux activities.

Various manufacturing techniques to process the solubilized formulations into oral dosage forms are also discussed in this chapter. For the formulations that are liquid under ambient conditions, encapsulation into soft gelatin or hard gelatin capsules is the most common manufacturing method. Semi-solid and solid-solubilized formulations that are liquid at a higher temperature (50–70°C) can be encapsulated into hard gelatin capsules as molten liquids at elevated temperature. Semi-solid or solid matrices are formed inside the capsules when the molten materials are cooled to ambient temperature. Spray congealing and fluidized bed melt granulation are

alternative manufacturing processes to convert the solubilized formulations with high melting/softening points into granules that can be readily processed into capsules or tablets. Powdered solution technology can also be applied to transform the solubilized formulation of low-dose drug into free flowing powder by absorbing the formulation into solid carriers.

5.1 Introduction

In solubilized formulations, excipients function as solvents to maintain drug molecules in the solution state in the final dosage forms. Application of solubilized formulations for enabling delivery of poorly water soluble drugs has attracted substantial research interest for developmental compounds and has been successfully applied to a number of low-solubility commercial products. This chapter focuses on the following three types of formulations: co-solvent-based, polyethylene glycol-based, and lipid-based formulations. Solubilized formulations based on polymeric solid dispersion, self-emulsifying formulation, and drug-cyclodextrins complexation technologies are covered in other chapters of this book. Properties of commonly used excipients for each type of formulations are presented in this chapter. Formulation development and selection of the manufacturing process for the finished dosage forms are discussed in this chapter as well.

5.2 Theoretical Modeling of Solubility in Co-solvents

The process of solubilizing a crystalline nonelectrolyte in a solvent thermodynamically consists of two steps: dissociation of the solute and mixing between the solute and solvent molecules. Noting that the dissociation process is analogous to melting, the solubility of a crystalline nonelectrolyte solute in a solvent is a function of the melting point of the solute and solute–solvent affinity. The extended Hildebrand equation ((5.1), Martin et al. 1982) has been derived to predict the solubility of drug in pure solvents and binary mixture of co-solvents:

$$-\text{Log } X_2 = \frac{\Delta H_f}{2} \cdot 2 \cdot 303RT \left(\frac{T_m - T}{T_m} \right) + \frac{V_2 \phi_1^2}{2} \cdot 2 \cdot 303RT \times (\delta_1^2 + \delta_2^2 - 2W)^2, \quad (5.1)$$

where 1 stands for solvent while 2 stands for solute. X_2 is the mole fraction of the solute, ΔH_f is the molar enthalpy of melting, R is the gas constant, T_m is the melting point of the solute, T is the absolute temperature (kelvin) at which the solubility is determined, V_2 is the molar volume of the liquid solute, Φ_1 is the volume fraction of the solvent, and δ is the solubility parameter.

The Solubility parameter is defined as the square root of the energy of vaporization per unit volume. It can be calculated using a group contribution method.

W is the interaction energy between the solute and solvent. The value of interaction energy cannot be calculated from fundamental physicochemical properties of the compound. However, W could be expressed as a power series of the solubility parameter of co-solvent:

$$W = C_0 + C_1\delta_1^1 + C_2\delta_1^2 + C_3\delta_1^3 + C_4\delta_1^4 + \dots \quad (5.2)$$

As shown in (5.1), low solubility of nonelectrolyte can be attributed to two factors: high melting point of the solute (a represented in the first term on the right-hand side of the equation) or low affinity between solute and solvent (represented in the second term on the right-hand side of the equation). The maximum solubility occurs when the intermolecular energy is the same for solute–solvent and solvent–solvent, and the second term on the right-hand side of the equation is equal to zero.

A log linear equation (5.3) describing the correlation the solubility of drug in binary aqueous system was derived by Yalkowsky et al. (1972):

$$\text{Log}S = \text{Log}S_w + \sigma F, \quad (5.3)$$

where S is the solute solubility (molar concentration) in water and co-solvent mixture, S_w is the solubility in water, F is the volume fraction of co-solvent, and σ , the linear regression coefficient, represents the solubilizing power of the co-solvent. This equation works very well when water–co-solvent system is more polar than the solute. As a general rule of thumb, the solubility parameter of solute needs to be at least three units lower than that of water–co-solvent mixture for the log linear regression to be applicable.

The solubility of poorly water-soluble drug in several different levels of co-solvent is experimentally measured. Log linear regression of the solubility data can then be used to predict solubility in co-solvent. The linear regression coefficient (slope of log linear regression) is indicative of the solubilizing power of the co-solvent.

Moore (1958) reported that different co-solvent mixtures with the same approximate dielectric requirement (ADR) can solubilize drug to the same extent. Approximate dielectric requirement can be calculated using (5.4):

$$\text{ADR} = \sum_{i=1}^n \frac{(\text{Wt.}\% \text{Solvent}) \times \text{Dielectric Constant}_i}{100}. \quad (5.4)$$

When changing to a different co-solvent system, the Moore equation can be used to identify a good starting percent for the new co-solvent.

5.3 Oral Absorption of Drug Substances

As shown in Fig. 5.1, orally administered drug can be absorbed in gastrointestinal (GI) tract through three different pathways: passive transcellular diffusion, active transcellular transport, and passive paracellular diffusion. These three absorption

Fig. 5.1 GI membrane transport for drug absorption (Lobenberg and Amidon 2000)

mechanism could occur simultaneously. For most drugs, passive transcellular transport through a highly lipophilic GI membrane is the primary absorption mechanism. Passive transcellular transport is governed by Fick's diffusion law, where the diffusion rate is directly proportional to the concentration gradient across the membrane. Intrinsic diffusion coefficient is dependent on the lipophilicity and size of drug molecules. The optimal $\text{Log}P$ for passive diffusion is 2–9. For ionizable drugs, it is the unionized species that permeates through GI membrane via passive transcellular pathway. Active transport is selective, could take place against a concentration gradient and is limited to drugs that are structurally similar to endogenous substances such as vitamins and sugars. Active transport can only occur at specific site in GI tract. Passive paracellular diffusion occurs through water-filled intercellular channels. In human, surface area of intestine available for paracellular diffusion only accounts for about 0.01% of total intestinal surface area. The channel diameter is in the range of 3–10 Å. Therefore, paracellular diffusion is only applicable to small molecules with a molar mass less than 200 dalton.

For BCS class II compounds, drug absorption is limited by the solubility in GI tract, while class IV compounds are limited by solubility and absorption constraints. The amount of drug absorption is proportional to drug concentration time permeability. Drug concentration in GI tract is a function of both solubility and dissolution rate. Drugs are dispersed at molecular level in the solubilized formulations. When the hydrophilic solubilized formulation comes into the contact with aqueous environment in GI tract, the dissolution rate is controlled by the disintegration rate of the formulation. As the excipient matrix dissolves, solubilized drug molecules go into the aqueous environment and stay supersaturated over a period of time. This fast dissolution and transient supersaturation allows for improved absorption. Simple lipid formulation and self-emulsifying formulation convert into coarse oil droplets or microemulsions in GI tract. Drug is at high concentration inside the oil droplets. These droplets function as reservoirs from which drug molecules can readily diffuse out to replenish free drug molecules in GI tract following the absorption. Solubility of drug is also improved by the presence of surface active ingredients in self-emulsifying formulation.

Drug absorbed in GI tract can enter either blood capillaries or lymphatic capillaries. Most drugs are absorbed into the portal vein because the fluid flow rate for blood capillaries is about 500× of that for lymphatic capillaries. Lipid excipients in simple lipid and self-emulsifying formulations have been shown to stimulate the intestinal lymphatic transport of poorly soluble drugs (Holm et al. 2003). Lymphatic absorption has several advantages over the portal vein absorption. The fraction of drug absorbed through lymphatic system is protected from first pass metabolism. For drug metabolized on first pass through the liver, lymphatic transport improves oral bioavailability. Surfactants, such as Tween 80, Cremophor EL, and vitamin E TPGS that are used in self-emulsifying formulations, are known to improve drug bioavailability by inhibition of P-glycoprotein-mediated efflux (Collnot et al. 2007) and by inhibition of CYP3A metabolism (Wu and Benet 2005).

5.4 Co-solvent-Based Formulations

Co-solvents are water-miscible organic solvents used to improve the solubility of poorly water-soluble drugs. They are used to support the preclinical studies in animal models to determine the pharmacokinetic profiles and toxicity profile of compounds in the drug discovery stage where exposure from a conventional crystalline system may be insufficient to elicit a response. Commonly used co-solvents for preclinical studies are ethyl alcohol, propylene glycol, low-molecular-weight PEG, glycerin, dimethylsulfoxide, and dimethylacetamide. However, only PEG, ethanol, propylene glycol, and glycerin demonstrate acceptable safety profile in long-term use to be included in commercial dosage forms (Nema et al. 1997). Physical properties of these four co-solvents are presented in Table 5.1. Glycerin and propylene glycol are more polar co-solvents than ethanol and liquid PEG. To achieve the optimum solubilizing capacity, co-solvents are often combined to yield a similar polarity to the drug substance.

5.4.1 Development of Co-solvent-Based Solubilized Formulations

Co-solvents are widely used to prepare concentrated drug solutions in parental and oral solution products. For parental drug delivery, the concentrated drug

Table 5.1 Properties of commonly used solvents at 25°C

| Solvent | Dielectric constant (ϵ) | Solubility parameter (Cal/cm^3) ^{1/2} | Surface tension (dynes/cm) |
|------------------|------------------------------------|---|-------------------------------|
| Water | 80.1 | 23.50 | 72.8 |
| Glycerin | 42.5 | 21.10 | 64.0 |
| Propylene glycol | 32.1 | 11.97 | 40.1 |
| Ethanol | 24.5 | 12.92 | 22.3 |
| PEG 400 | 12.4 | 11.30 | 44.5 |

solutions are often diluted with saline solution and delivered to patient via IV infusion. Ethanol and propylene glycol alone or in combination are the most common co-solvent systems in injectable products (Nema et al. 1997). The amount of ethanol or propylene glycol in the formulation ranges from 0.2 to 80% glycerin has been used in injectable at level as high as 80%. PEG 300 and PEG 400 are used in injectable products at level as high as 65%. Polyethylene glycol undergoes auto-oxidation (Hamburger et al. 1975) and the peroxides generated can induce drug degradation. Therefore, application of PEG as a co-solvent for injectable products is limited. Co-solvents not only need to achieve higher solubility but also need to prevent drug precipitation upon dilution. Co-solvents can also be used to suppress chemical degradation of drugs by altering the dielectric constant of the medium (Zhao and Yalkowsky 2001).

Co-solvents are also commonly used in oral solutions and soft gelatin capsules for poorly soluble compounds. The advantage of oral solution is that it is easier to administer solution to pediatric patients and adults having difficulty in swallowing. Sweetening agents are needed for solutions containing propylene glycol which is known for its bad taste. In the case of self-emulsifying formulations, the presence of co-solvents not only improves the solubility of drug in the formulation but also facilitates the emulsification in aqueous medium. In combination with vitamin E TPGS, PEG-400 and propylene glycol are present in oral solution and soft gelatin capsule products of amprenavir (Agenerase®). Self-emulsifying soft gelatin capsules of cyclosporine (Sandimmune®) contain glycerol, propylene glycol, and ethanol as co-solvents. Co-solvents facilitate the emulsification process via “diffusion and stranding” mechanism (Pouton 1997). Co-solvents dissolve the water-soluble component into aqueous environment as a solubilized system. With further migration, co-solvent gets diluted and can no longer maintain a single phase consisting of water, oil, and co-solvent. As a result, the oil phase separates out as fine oil droplets.

5.5 Polyethylene Glycol-Based Solid Dispersion

Polyethylene glycol-based solid dispersion for poorly water-soluble drugs has attracted a great deal of research interest over the last 30 years. PEG is an ideal excipient for the preparation of hydrophilic solubilized formulation. It has low enthalpy of fusion (2.5 kJ/mol), low melting point, and low viscosity in molten state. It also has good solvent capacity in its molten state. Classification of drug-PEG dispersions is presented in Table 5.2 (Craig 1990). Improved bioavailability from these systems is attributed to the increase in surface area of drug substance, solubilization, and improved surface wetting of drug particles in the microenvironment with concentrated PEG (Chiou and Riegelman, 1971).

High-molecular-weight PEG has an average molar mass ranging from 3,350 to 8,000. They are manufactured by Dow Chemical under the trade name Carbowax™ Sentry™. It is semi-crystalline material with a high degree of crystallinity. With melting points ranging from 45 to 65°C, PEGs of high-molecular-weight are solid

Table 5.2 Classification of drug dispersions in PEG

| Classification | Properties |
|------------------------|--|
| Eutectic mixture | <ul style="list-style-type: none"> • Negligible solid–solid solubility • Thermodynamically, the composition is an intimately blended physical mixture of drug crystals and PEG crystals • The system is thermodynamically stable |
| Solid solution | <ul style="list-style-type: none"> • Drug molecules could also be present in the parallel helix unit cell of the crystalline phase of PEG • Covalent nature of PEG crystal lattice makes the solubilization of drug molecules in PEG crystalline phase difficult |
| Glass solution | <ul style="list-style-type: none"> • Drug molecules are predominately solubilized in the amorphous region of PEG semi-crystalline structure • The system is not thermodynamically stable. Crystallization of drug can take place when the composition is exposed to high-humidity and high-temperature environment |
| Amorphous precipitates | <ul style="list-style-type: none"> • Drug and PEG exist in two different phases • Drug phase is amorphous • The system is not thermodynamically stable. Crystallization of drug can take place when the composition is exposed to high-humidity and high-temperature environment |

under room temperature. Above the melting point, PEG becomes a low viscosity liquid. At 80°C, viscosity of molten PEG ranges from 150 (PEG 3350) to 1,500 cP (PEG 8000). In the solid state, PEG forms lamellar structure with alternating crystalline and amorphous regions. The crystal lattice of PEG consists of two parallel helices in a unit cell.

5.5.1 Development of PEG-Based Solubilized Formulations

PEG is a large molecule with a covalent crystal lattice. In contrast, most drugs form molecular or ionic crystals. The lattice mismatch between PEG and drug makes the formation of a true solution difficult. When the drug does not interact with PEG strongly, a two-phase solid is formed. The two-phase system could be a simple eutectic mixture, which is thermodynamically stable mixture of intimately blended crystalline drug domains and semi-crystalline PEG domains. Enhanced drug absorption from eutectic mixture is attributed to the large surface area and improved wetting of micronized or sub-micron drug crystals. For formulations of eutectic mixtures, molten PEG must have good solubilization capacity for the drug substance. In the melt method, processing drug and PEG at the eutectic point allows for the low processing temperature to minimize drug degradation. Eutectic mixture formulation strategy has been successfully applied to develop rapidly dissolving mixtures of PEG 8000 and fenofibrate which resulted in a tenfold increase in fenofibrate dissolution (Law et al. 2003). Differential scanning calorimetry, hot stage

microscopy, and variable temperature X-ray diffraction techniques can be used to determine the phase diagram of these systems and were applied to the PEG 8000 and fenofibrate composition. Crystalline drug and semi-crystalline PEG phases were identified in samples across all drug loadings. At the eutectic point was identified to be at 20–25% drug loading. The drug–PEG eutectic crystallization led to the formation of irregular microstructures. Fenofibrate crystal in the microstructure was less than 10 μm .

For drug substances that demonstrate good glass forming properties (T_g/T_m (in kelvin) $>2/3$) and strong interaction with PEG, a physically stable solid dispersion consisting of amorphous drug phase and semi-crystalline PEG phase could be successfully prepared. Since the only difference in the liquid PEG and solid PEG is the degree of polymerization, interaction between drug and low-molecular-weight liquid PEG is indicative of the interaction between drug and high-molecular-weight PEG. In the presence of small amount of high-molecular-weight PEG, improvement in the solubility of drug substance in aqueous medium is also a good indicator of drug and PEG interaction. Solubility of parabens in liquid PEG (PEG 400) has been used to predict the interaction between parabens and high-molar weight PEG (PEG 4000) (Unga et al. 2009). Law et al. (2003) have developed amorphous PEG 8000-ritonavir solubilized solution. High T_g/T_m ratio indicates that ritonavir is a good glass former. Amorphous ritonavir is reasonably stable at ambient conditions. Solubility of crystalline ritonavir improved in the presence of PEG markedly. Solubility of ritonavir in the amorphous state is ten times the solubility of crystalline drug. PEG was found to have negligible effect on the glass transition temperature of ritonavir. The formulation was moisture sensitive. Crystallization of amorphous ritonavir was observed when the composition was exposed to high humidity environment. However, the formulation was chemically and physically stable when the composition was protected from the moisture with proper packaging configuration. Even at 30% drug loading, ritonavir solid dispersion in PEG 8000 was stable under dry condition for >1.5 years. The presence of ritonavir did not affect the PEGs 8000 enthalpy of fusion. It was concluded that the solid dispersion consisted of two phases: crystalline PEG 8000 and amorphous phase comprising a mixture of amorphous ritonavir and amorphous PEG. Good stability of the ritonavir-PEG 8000-solubilized formulation was attributed to the intrinsic stability of amorphous ritonavir and the stabilization effect of PEG.

Due to the unique crystalline structure and high crystallinity of PEG, formation of interstitial solid between PEG and drug is not common and can only occur at low drug loading. When drug is present in the crystal lattice of PEG, changes in thermal properties of PEG, such as lower melting point and low enthalpy of melting, can be observed. Interstitial solid solution of clofibrate in high-molecular-weight PEG has been reported (Anguiano-Igea et al. 1995). In the presence of clofibrate, PEG melting point shifted to a lower temperature and the broadening of the melting peak was also observed. Drug release rate increased with an increase in the molecular weight of PEG and PEG/drug ratio.

When drug is dispersed at the molecular level in PEG matrices, drug molecules can be dissolved either in the amorphous domain or in the helix interstitial space of crystalline domain. It is believed that most of drug molecules are present in the

amorphous domain of PEG. As pointed previously, the amount of drug that could be truly dispersed at molecular level in PEG-based solid dispersion is limited since PEG is a highly crystalline material. The limited commercial success with PEG-based solid dispersions is attributed to (1) low drug-loading capacity as the result of high crystallinity of PEG and (2) poor chemical stability of drug substances associated with the system as the result of PEG-induced oxidation. Gris-PEG[®] (griseofulvin in PEG 400 and PEG 8000 mixture) and Aprical[®] (Nifedipine in PEG 300 and PEG 6000 mixture) are the only two market products containing PEG-based solid dispersion. Gris-PEG[®] is a eutectic mixture of griseofulvin and PEG. Drug is present as ultra-microsize crystals in Gris-PEG[®]. Nifedipine is solubilized in Aprical[®]. Nifedipine is highly soluble in both the liquid low-molecular-weight PEG and the melt of high-molecular-weight PEG (Hohne et al. 1990). When high-molecular-weight PEG is used, nifedipine dissolves easily in molten PEG. However, nifedipine crystallizes out of the formulation when molten PEG solidifies at ambient conditions. The product was successfully developed when a mixture of liquid PEG and solid PEG is used. Incorporation of PEG 300 increases the amorphous content of the PEG matrices, and no crystallization of nifedipine is observed during the storage.

Pharmaceutical scientists have been studying different formulation and process approaches to decrease the crystallinity of high-molecular-weight PEG in order to improve the drug-loading capacity of PEG-based drug delivery systems. Polymers and surface-active excipients have been used to inhibit the crystallization of drug substances. Strong hydrogen bonding or hydrophobic interactions between these excipients and drug molecules reduces the mobility of drug molecules and hinders the molecular packing in crystal lattice. The same principles could be used to reduce the crystallinity of high-molecular weight PEG. Shock freezing of PEG melt has been studied to inhibit crystallization of PEG; however, due to the low glass transition temperature (-60°C) recrystallization occurs during storage which limits the effectiveness of quenching. Tertiary systems comprising poorly soluble drug, high-molecular-weight PEG, and stabilizer have been investigated to increase the amorphous content of PEG to improve the drug loading and to prevent drug from crystallizing during the storage. Bley et al. (2010) used Povidone and Copovidone to stabilize nifedipine in PEG 1500. The stabilized drug/polymer/PEG dispersion demonstrated more consistent dissolution characters, compared to PEG solid dispersions, which contained a higher amount of crystalline drug. Inclusion of sodium lauryl sulfate in naproxen-PEG 4000 solid dispersion further enhanced the dissolution properties of the solid dispersion. After 30 months of storage at ambient conditions, there was no change in physicochemical characteristics and the dissolution properties of solid dispersion Mura et al (1999).

5.5.2 Fusion Method for the Preparation of Solid Dispersion

Drug is dissolved in molten PEG in fusion method. The molten mass solidifies when it cools to ambient temperature. Simplicity of the manufacturing process is the biggest advantage of fusion method. Degradation of the drug at the elevated processing

temperature limits fusion methods application to thermally stable compounds. For thermally labile drugs that form an eutectic mixture with PEG, a mixture of PEG and drug at eutectic ratio can be used to reduce the processing temperature since the eutectic mixture melts at a temperature much lower than either of the melting points of the individual components. Various techniques, such as pouring the molten mass to metallic plate and quenching the molten mass with liquid nitrogen, have been explored in the laboratories. Alternatively, the molten mass can be filled directly into hard shell capsules (gelatin or HPMC capsules). Crystallization of PEG is dependent on the temperature of PEG melt. Properties of the PEG-based solid dispersion prepared with the melt method are also known to be cooling rate dependent. Rapid quenching during the preparation process, low storage temperature, and low relative humidity were found to prevent crystallization of nimodipine from its solid solution in PEG 2000 (Urbanetz and Lippold 2005).

5.5.3 Solvent Method for the Preparation of PEG Dispersion

In the solvent method, a homogeneous organic solution containing drug and PEG is prepared. Processing techniques such as rotary evaporation, spray drying, and lyophilization, are applied to remove the organic solvents. Drug degradation is minimized or avoided in solvent method. However, the difficulties associated with organic solvents handling and complete removal of the organic solvents present unique challenges with solvent method.

With the extensive research interest in the application of supercritical fluid in pharmaceutical processing, supercritical CO₂ as an alternative solvent to prepare drug-PEG dispersion has been demonstrated. Where drug has sufficient solubility in supercritical CO₂, rapid expansion of supercritical fluid solution (RESS) process is safer and more environmentally friendly than organic solvent processes. In RESS process, drug and PEG solution in supercritical CO₂ is passed through a small nozzle and allowed to expand rapidly under ambient condition. When CO₂ was converted to gas, solid dispersion of very fine particle size and uniform size distribution formed. With the rapid flashing of supercritical CO₂ and solidification of the drug dispersion, PEG processed with RESS process has higher amorphous contents than that processed with traditional solvent-based process and fusion process. Higher amorphous content would potentially allow higher drug loading. Concentration of drug and PEG, processing temperature, and flow rate of the solution through the expansion nozzle can be controlled to produce drug-PEG dispersion with different morphology. Brodin et al. (2003) successfully applied RESS process to prepare lidocaine and PEG 8000 dispersion.

For the drug substance with limited solubility in supercritical CO₂, a gas anti-solvent recrystallization (GASR) process has been developed. The GASR process is a more universal process than RESS process since supercritical CO₂ has limited solvent capacity for most drug substances. Complete miscibility of organic solvent with supercritical CO₂ is required for GASR process. When organic solution of drug

and PEG is mixed with supercritical CO₂, carbon dioxide is dissolved in and expands the organic solvent under moderate temperature and pressure. The solubilization power of organic solvent decreases when CO₂ is incorporated. When organic solvent can no longer keep drug and PEG in solution, nucleation of drug-PEG dispersion starts to form. As more CO₂ is mixed in the solution, the nuclei continue to grow until the drug-PEG completely precipitates out of the solvent.

Moneghini et al. (2001) used supercritical CO₂ as the anti-solvent to recover carbamazepine-PEG 4000 solid dispersion from its acetone solution.

5.6 Lipid-Based Formulations

Natural and synthetic lipids have been widely applied to improve the bioavailability of poorly soluble drugs. The mechanisms of improved absorption from lipid-based solubilized formulations are: (1) enhanced dissolution and solubilization in vivo; (2) prolongation of gastric residence time; (3) stimulation of lymphatic transport; (4) affecting intestinal permeability; and (5) reduced metabolism and efflux activities. Lipid excipients commonly used in solubilized formulations include natural oils, fatty acids, and partial glycerides (Dahan and Hoffman, 2008; Trevaskis et al. 2008). Pouton (2000) classified lipid-based formulations into four different categories on the basis of their composition and they are listed in Table 5.3. In the simplest lipid-based formulations (type I), drug is dissolved in glycerides. Digestive products of glycerides mixed with bile salts in GI tract create mixed micelles where drug remains solubilized. The micelles function as drug reservoirs from which drug molecules diffuse out into the digestive tract and get absorbed. Drug loading in type I formulation is limited due to low solvent capacity of glycerides. In type II formulations, surfactants of low HLB values are incorporated to improve the emulsification of glycerides. Because digestion of glycerides plays a critical role in drug absorption, there is a poor correlation between in vitro and in vivo behaviors for type II formulation. Improved emulsification (faster emulsification and smaller oil droplets) in vitro does not always result in improved drug absorption. Surfactants of high HLB values along with hydrophilic co-solvents are incorporated into type III formulations. Presence of these excipients greatly improves not only the solvent capacity but also the emulsification properties of the formulation. Type III formulations are also termed as self-emulsifying formulations. Hydrophilic surfactant and co-solvents in the formulation allow this type of composition to emulsify rapidly and spontaneously in aqueous medium. With proper composition design, the resulting nanoemulsion type III formulation can be optically clear. Absorption of drug is enhanced with the large surface area of emulsified droplets. Cyclosporine is a poorly soluble compound and it was initially marketed as Sandimmune® soft gelatin capsules containing cyclosporine solution in ethanol. Neurol® soft gelatin capsule, a type III formulation, was later marketed for the delivery of cyclosporine. The capsule contains Labrafil M-2,125 M as hydrophilic surfactant, and ethanol and glycerin as the co-solvents. In comparison with Sandimmune® capsules, Neurol® capsules demonstrated improved

Table 5.3 Lipid formulation classification system

| Composition | Content of formulation (%) | | | | |
|--------------------------------------|-----------------------------|-------------------------------|--|--------------|---------|
| | Type I | Type II | Type IIIA | Type IIIB | Type IV |
| Triglycerides or mixed glycerides | 100 | 40-80 | 40-80 | <20 | – |
| Water-insoluble surfactants (HLB<12) | – | 20-60 | – | – | 0-20 |
| Water-soluble surfactants (HLB>12) | – | – | 20-40 | 20-50 | 30-80 |
| Hydrophilic co-solvent | – | – | 0-40 | 20-50 | 0-50 |
| Particle size of dispersion (nm) | Coarse | 100-250 | 100-250 | 50-100 | <50 |
| Significance of aqueous dilution | Solvent capacity unaffected | Some loss of solvent capacity | Significant phase changes and potential loss of solvent capacity | | |
| Significance of digestibility | Crucial requirement | Not crucial, likely to occur | Not crucial, may be inhibited | Not required | |

absorption in regards to rate, extent, and dose linearity. In addition, food effect observed with Sandimmune[®] capsules is not present with Neurol[®] capsules. This chapter is focused on the formulation development of type I lipid formulation. Detailed discussion on type II and III formulations is presented in Chap. 10.

5.6.1 Triglycerides

Triglycerides are lipids consisting of one glycerin and three fatty acid molecules. On the basis of the C–C backbone composition, triglycerides can be classified as saturated (no C=C bond in C–C backbone) and unsaturated (C=C bond in C–C backbone) triglycerides. Saturated triglycerides are also called “fat,” which are solids at room temperature. On the basis of fatty acids carbon backbone length, triglycerides can be classified as short-chain (<6 carbon), medium-chain (6–12 carbon), and long-chain (>12 carbon) triglycerides. Refined natural oils are commonly used for the delivery of poorly soluble drugs. Refined natural oils are unsaturated, long-chain triglycerides consisting of triglyceride of fatty acids, small amount of free fatty acids, and plant sterols. Most commonly used refined natural oils are coconut oil, corn oil, soybean oil, and sesame oil. These oils differ in the chain length of fatty acids, and the number and position of unsaturated bonds. At the initial stage of

production for refined natural oils, crude natural oils are obtained from the plant seeds by expression in a hydraulic press or by solvent extraction. The refining process includes several critical steps to ensure product quality, such as: the removal of impurities such as free fatty acids and phospholipids; decolorizing with activated carbon; and deodorization with steam. In many cases, these natural materials may still contain trace levels of residuals which may have a detrimental impact on critical product attributes. Many new grades of excipients now rely on novel technologies to improve product purity, such as Flash Chromatography, which was applied by Croda to effectively minimize unwanted residuals such as moisture, catalyst, peroxides, and aldehydes. Materials produced by Croda with this technology are referred to as Super Refined™ natural oils and serve as only one example of higher-purity natural excipients which are now commercially available.

Medium-chain triglycerides are liquid at room temperature. Medium-chain triglycerides are chemically synthesized via re-esterification of glycerol with medium-chain fatty acids (caprylic and capric fatty acids). Medium-chain fatty acids are produced via the hydrolysis of fixed oils and the distillation processes. Coconut oil is the primary source for medium-chain fatty acid. Being more polar than long-chain triglycerides, medium-chain triglycerides have better solvent capacity.

5.6.2 Mixed Glycerides and Fatty Acids

Mixed glycerides are manufactured through transesterification or direct esterification. In transesterification process, triglycerides react with glycerol under heating with alkaline catalysts. Direct esterification takes place between the selected fatty acids and glycerol. Mixed glycerides are mixtures of fatty acids, glycerol, mono-, di-, and triglycerides. Due to the nature of manufacturing processes, compendial specifications for mixed triglycerides allow for variations in the composition. Formulation scientists must pay close attention to the compositional difference between the materials from different manufacturers and between different batches from the same manufacturer. Fatty acids are more polar than corresponding glycerides. Oleic and linoleic acids are two most commonly used fatty acids for improving bioavailability of poorly soluble compounds. Oleic acid is particularly a good solubilizer for poorly soluble drugs. Ion pairing between oleic acid and basic drugs also contributes to good solubilizing capacity of fatty acids. Only oleic acid has been approved for use in oral dosage forms at a maximum potency of 598.60 mg per FDA's Inactive Ingredient's List.

5.6.3 Handling of Lipid Excipients

Lipid excipients are mixtures of various components. Segregation of these components could take place during the shipping and handling. For semi-solid lipids, it is recommended to melt the entire contents in the container, mix well, and subdivide to

appropriate smaller aliquots for future use. This practice would ensure the homogeneity of the contents and minimize the heat stress from repetitive heating of the materials. For lipids containing unsaturated C=C bonds, exposure to heat, humidity, and light should be minimized since C=C bonds undergo oxidation under those conditions. Nitrogen purging of the headspace of the containers for unsaturated lipids is highly recommended.

5.6.4 Development of Lipid-Based Solubilized Formulations

The simplest lipid formulation consists of drug solubilized in triglycerides. The manufacturing process is simple and the formulation is biocompatible. Stabilizers such as antioxidants and chelating agents are commonly included in lipid-based formulation to improve the stability of lipid vehicles and to prevent excipient-induced drug degradation. Solvent capacity of triglycerides is generally low (<10 mg/mL). In comparison with long-chain triglycerides, medium-chain triglycerides have higher solvent capacity. Triglycerides are mainly applicable for drug substances whose poor water solubility was attributed to their hydrophobicity (Log P > 5) and their instability to interact with water molecules. Triglycerides are not suitable for drugs whose poor water solubility is attributed to strong crystal lattice energy (high melting point and high enthalpy of fusion). Vesanoïd® (tretinoin, vitamin A analog, 10 mg) and Accutane® (isotretinoin, 10, 20, and 40 mg) are two commercial examples where a mixture of hydrogenated soybean oil and soy bean oil is used as the formulation vehicle. Medium-chain triglyceride (fractionated triglyceride of coconut oil) is used for manufacturing Rocaltrol® (vitamin D analog, 0.25 and 0.5 µg) capsules. Vesanoïd® and Accutane® capsules contain butylated hydroxytoluene (BHT) and EDTA, while Rocaltrol® contains BHT and butylated hydroxyanisol (BHA).

In gastro-intestinal tract, drug-containing triglycerides are initially dispersed into coarse oil droplets. Triglycerides are then rapidly digested by lipase/co-lipase to free fatty acids and 2-mono-glycerides. Even a small amount of long chain lipids (1–2 g), typically amount present in the dosage form, is sufficient to stimulate gall bladder contraction and therefore elevate bile salts, phospholipid, and cholesterol level in small intestine (Kossena et al. 2007). These biliary lipids in combination with the lipid digestion products create a variety of colloidal species, including emulsion droplet, micelles, mixed micelles, and vesicles. These colloidal species are capable of maintaining drug in the solubilized state to improve the absorption in intestine.

Since the digestion of lipid excipients plays a crucial role in the absorption of poorly soluble drug, absorption of drug in triglyceride-based formulations is dependent on the composition of lipid vehicle. Medium-chain triglycerides are digested more readily than long-chain triglycerides. Therefore, faster absorption is often observed with medium-chain glyceride-based formulations. Digestive products of long-chain triglycerides enhance lymphatic transportation to greater extent than that of medium-chain triglycerides. For compound with significant lymphatic absorption,

Fig. 5.2 Schematic diagram to show the likely colloidal species formed on digestion of different quantities of medium- and long-chain lipids and the coincident drug distribution pattern obtained at the end of 60 min (50 mg lipid) or 30 min (250mg lipid) *in vitro* digests. The *dotted lines* encircle those species present in the aqueous phase obtained by centrifugation of the digests, the *dashed line* signifies the pellet, and the *solid lines* any partially digested and poorly dispersed lipid phases. (The diagrammatic representations used to denote mixed micelles and vesicles are purely illustrative and are not meant to imply specific structural details.) (Porter et al. 2004)

long-chain triglyceride-based formulations provide better absorption. Porter and coworkers performed *in vitro* lipolysis of triglyceride formulation of halofantrine to investigate the types of lipids and the amount of lipids on the colloidal species formed *in vivo* (Porter et al. 2004). The schematic diagram of likely colloidal species is presented in Fig. 5.2. Higher bioavailability of probucol in rats was observed when long-chain triglyceride was used to replace medium-chain triglycerides (Palin and Wilson 1984). Enhanced lymphatic transportation due to the digestive products of long-chain triglycerides was determined to be the contributing factor for greater absorption. In the case of griseofulvin, better absorption was observed with medium-chain than long-chain triglycerides (Dahan and Hoffman 2007). This improvement in absorption was resulted from more rapid digestion of medium-chain triglyceride.

For triglyceride-based formulations, there is no concern over drug precipitation *in vivo* when the formulation is diluted by the aqueous contents in GI tract. However, triglycerides low solvent capacity has limited the application of lipid solutions for

drug delivery. Solubility capacity of intestinal colloidal phases during the digestion of lipid formulations was far greater higher than the solubility capacity of lipid excipients *in vitro*. Suspension formulation in lipids may prove to be beneficial as the solubilization capacity of the colloidal phases produced on digestion of the lipid vehicle is likely to be greater than the dose of drug that could otherwise be administered as a lipid solution. The hypothesis was proved in delivering griseofulvin and danazol as oil suspensions (Kaukonen et al. 2004). Commercial progesterone capsule (Prometrium®) is formulated as the micronized progesterone dispersed in peanut oil. When micronized progesterone was formulated as the oil suspension, its peak plasma concentration increased by threefold in a animal PK model (Hargrove et al. 1989).

Even though triglycerides are not miscible with water, they always contain a small amount of water (<0.1%). It is important to understand the effect of water content on drug solubility in triglycerides. Hydration of triglycerides caused a significant decrease in the solubility of estradiol and testosterone, which may form hydrate or hemihydrates with the water in triglycerides (Land et al. 2005).

Mixed glycerides and fatty acids are more polar and have higher solubilizing capacity than triglycerides. For high-dose drug products, mixed glycerides and fatty acids are typically used. Fortovase® (Saquinavir free base, 200 mg) is based on mono- and diglycerides. The formulation contains vitamin E as an antioxidant. Restandol® (testosterone undecanoate 40 mg) contains drug solubilized in oleic acids. Oleic acid was used to improve the absorption of cinnarizine, a weak base compound. Oleic acid formulation improved C_{max} and AUC over the traditional table formulation by 2.9- and 3-folds, respectively (Tokumura et al. 1987). Holm et al. (2001) investigated the effect of fatty acids degree of unsaturation on absorption of halofantrine free base. Three different fatty acids (oleic acid, linoleic acid, and linolenic acid) were used in the study. Bioavailability was the same for all three formulations. However, lymphatic transportation was fatty acid dependent. Lymphatic transportation for linoleic formulation is 16.6× higher than that for linolenic acid formulation.

As shown in Table 5.3, hydrophilic surfactants and water-soluble co-solvents are often added in simple lipid formulations to prepare self-emulsifying drug-delivery systems. This type of formulation is engineered to disperse into fine oil droplets (<10 μm) rapidly in the stomach and empty quickly into intestine. Emulsification of this type of formulation does not rely on the bile salts in GI tract, and fine oil droplets provide large surface area for drug partition. Drug absorption of self-emulsifying delivery system is more rapid and more consistent from patient to patient. In comparison, drug absorption from type I system is slower and is influenced more by the GI environment. However, for compounds with a narrow therapeutic window and sufficient solubility in lipids, type I systems are more desired.

Juppo (2004) developed a multiparticulate modified release solubilized formulation of felodipine to improve the absorption and to achieve more consistent plasma concentration. The matrix consisted of at least one hydrophobic matrix former and one hydrophilic matrix former. Cetyl alcohol, PEG 4000, Poloxamer 407, hydrogenated vegetable oil, glyceryl palmitostereare, glyceryl behenate, and stearic acid have all been demonstrated to be suitable carriers for preparing felodipine lipid solution.

Traditionally, *in vitro* characterization of lipid formulation focuses on the dispersability of oil phase and the particle size of the dispersed oil phase when the formulation contacts aqueous environment. As discussed previously, *in vivo* performance of the solubilized lipid formulation is dependent on the digestive products of the lipids. Biorelevant *in vitro* lipolysis models have been established to simulate lipid digestion in small intestine. In lipolysis processes, formulation is mixed with bile salt, phospholipid, and buffer at 37°C in a pH-stat using NaOH as titrant to maintain pH. Different levels of bile salt and phospholipid can be used to simulate fast or fed state. Lipolysis processes are initiated with the addition of pancreatic extract. The mixture is sampled at different time points to determine the amount of drug solubilized (Kaukonen et al. 2004).

5.7 Other Solubilized Systems

Other formulation strategies to develop solubilized formulations include drug–cyclodextrins complex, amorphous solid dispersion, and self-emulsifying formulation. Below is a brief overview of these three types of formulations. The reader is referred to Chaps. 7 and 10 for the in-depth discussion of drug–cyclodextrins molecular complex and self-emulsifying systems. Preparation of amorphous solid dispersion via spray drying and melt extrusion are covered in Chaps 8 and 9.

5.7.1 Drug–Cyclodextrins Complex

Cyclodextrins (CD) are cyclic oligosaccharides derived from starch. CD molecules take the shape of a truncated cone. The hydroxyl groups of CDs are at the exterior of the cone structure, leaving the interior of the cone a hydrophobic environment. Hydroxypropyl and sulfobutylether derivatives of CDs have been synthesized to improve the solubility of CDs for broader application. CDs have a safe toxicological profile with little oral absorption. CDs that are absorbed are excreted unchanged in the urine. CDs have been used in formulating poorly water-soluble drugs. Itraconazole oral solution, marketed as Sporanox, contains 2-hydroxypropyl- β -cyclodextrin. Vfend[®], IV solution of Voriconazole marketed in Europe, contains sulfobutylether β -cyclodextrin.

Thermodynamic driving forces for the formation of CD inclusion complexes include: (a) hydrophobic interaction between inner cavity of CD and drug; (b) release of “high-energy water” from the CD cavity; and (c) release of conformational strain in a CD-water adduct. Phase solubility diagram of the concentration of dissolved drug as the function of CD concentration is constructed to determine drug to CD ratio, binding constant, and the complexation efficiency (Connors 1996). Depending on the solubility of formed complex, drug–CD complexation can be classified into two different categories (Fig. 5.3). In type A systems, solubility increases with increase in CD concentration. Type B profile is indicative of the formulation of

Fig. 5.3 Phase solubility profile drug in cyclodextrins solution: A and B types (with applicable sub-types) (Connors 1996)

drug-CD complex with limited water solubility. Studies have shown that drug-CD complex itself can also aggregate that can further enhance drug solubility. In most cases, the drug and CD complex is at 1:1 ratio and of A_L type. Dilution of the solution will not result in supersaturation, which could induce precipitation. However, for compound with very low intrinsic solubility, drug must have a strong affinity with CD to achieve desired enhancement in solubility.

Kneading methods can be used to complex insoluble drug and CDs. Drug substance is added into slurry of CD. The mixture is kneaded until a paste is produced. Small amount of organic solvent is often used to improve the solubility of drug in the slurry to facilitate the drug inclusion process. However, excessive amount of organic solvent could impede the complexation process by competing with drug substance for inclusion in CD cavity. For poorly water-soluble drug with pH-dependent solubility profile, solution method is the most practical mean to product drug-CD complex. Drug and CD are initially dissolved in water adjusted to certain pH to keep drug in the solution. Neutralization agent is then incorporated into the solution to gradually reduce the drugs solubility in the aqueous medium. The decrease in solubilization capacity would drive drug into the cavity of the CD.

5.7.2 Self-Emulsifying Formulation

Self-emulsifying formulations transform into stable emulsion spontaneously when they are dispersed in aqueous environment. The presence of bile salts and digestive

products of glycerides in the formulation is not required for the emulsification process. Self-emulsifying formulation consists of drug, oil, high HLB surfactant, and co-solvent. Improved drug absorption of poorly soluble drug from self-emulsifying formulation is due to the large surface area of the emulsion. Self-emulsifying formulations also offer the advantage of more rapid absorption onset and more consistent absorption under different GI conditions such as food effect and pH effect.

The best-known example of marketed self-emulsifying drug product is cyclosporine formulation. Earlier formulation contains corn oil, ethanol, and labrafil. The formulation disperses into coarse emulsion in aqueous medium. The improved formulation, also known as Neoral™, consists of mixed glycerides as the oil phase, Cremophor as emulsifying surfactant, and propylene glycol and ethanol as the co-solvents. The formulation forms a thermodynamically stable transparent nanoemulsion when dispersed into aqueous medium. Improved absorption from Neoral™ formulation was attributed to better dispersability of the formulation. Surfactants used in self-emulsifying formulations have also been reported to enhance drug absorption by inhibition of P-glycoprotein-mediated efflux (Collnot et al. 2007) and by inhibition of CYP3A metabolism (Wu and Benet 2005).

The predominant mechanism of self-emulsification is “diffusion and stranding” driven by osmotic pressure imbalance (Pouton 1997). Construction of ternary surfactant–oil–water phase diagram is crucial to understanding the role of each component. Selection of the formulation should be based not only on the how readily the formulation self-emulsifies but also on the stability of the emulsion.

5.7.3 Amorphous Solid Dispersion in Polymer Matrices

Amorphous solid dispersion is a single-phase system consisting of preferably amorphous polymer as the carrier, drug in its high-energy state, and other excipients such as processing aid, recrystallization inhibitor, and wetting agent. Drug molecules are dissolved in polymeric formulation matrix. Three-dimensional long-range order of drug molecule in crystalline state is absent in amorphous solid dispersion. Hydrogen bonding and hydrophobic interactions between the drug and polymer are the primary driving forces for the formation of the solid dispersion during melt extrusion, inhibition of drug crystallization during storage, and achievement and sustainment of supersaturation in GI tract. Copovidone, povidone, HPMCAS, and HPMC have been successfully used as the carriers in commercial products.

In vivo, drug molecules released from the amorphous dispersion are in four different states: (1) free drug molecules; (2) amorphous drug/polymer nanostructures; (3) aggregates of amorphous drug/polymer nanostructures; and (4) amorphous or crystalline precipitates. Supersaturation of free drug molecules and the rapid release of drug from drug/polymer nanostructures are two contributing factors for achieving higher bioavailability. An example of supersaturation and sustainment of supersaturation of amorphous drug alone and a solid dispersion in aqueous media is shown in Fig. 5.4 (Friesen et al. 2008). Supersaturation as high as 100-fold has been reported

Fig. 5.4 Microcentrifuge dissolution data comparing crystalline drug, amorphous drug, and amorphous solid dispersion (Friesen 2008)

for amorphous drug. The solubility ratio (amorphous over crystalline) drug can be theoretically calculated using the difference in the heat capacity of crystalline state and amorphous state at the glass transition temperature (Hancock and Parks 2000).

Solvent-based spray drying, melt extrusion, and solvent-based drug layering processes could be used to prepare amorphous drug dispersion in polymeric carriers. The reader is referred to Chaps. 8 and 9 for the in-depth discussion of spray drying and melt extrusion for solid dispersion.

5.8 Dosage Form Manufacturing of Solubilized Formulations

Various manufacturing techniques process the drug solution in carrier excipients into oral dosage forms. Selection of the proper process depends on the physical characteristics of the solubilized formulations. For solubilized formulations that are liquid under room temperature, encapsulation in soft gelatin capsule is the most common manufacturing approach. Absorption of liquid formulation into excipients (powered solution) with large surface area has attracted a great deal of research interest. Due to the low liquid-carrying capacity of pharmaceutical excipients, there has been no commercial success with powdered solution technology. For solubilized formulations that are molten low-viscosity liquids at the elevated temperature and semi-solid or solid at the room temperature, direct filling into hard gelatin capsules is a practical choice. In comparison with soft gelatin encapsulation, hard gelatin encapsulation is simpler and a more efficient manufacturing process. There is also less interaction between the capsule shell and fill material in hard gelatin encapsulation.

Table 5.4 Example composition of commercial soft gelatin capsule products

| Product | Active ingredient | Composition of the solubilized formulation |
|-----------|-------------------|--|
| Adalat | Nifedipine | Peppermint oil, PEG 400 |
| Procardia | Nifedipine | Peppermint oil, PEG 400, glycerin |
| Accutane | Isotretinoin | Soybean oil, hydrogenated vegetable oil and hydrogenated soybean oil, Sodium EDTA, BHA |
| Vesanoid | Retinoin | Soybean oil, hydrogenated vegetable oil and hydrogenated soybean oil, Sodium EDTA, BHA |
| Rocaltrol | Calcitriol | Fractionated triglyceride of coconut oil, BHA, BHT |
| Fortase® | Saquinavir | Medium chain nono- and diglycerides, povidone, vitamin E |
| Acodart | Dutasteride | Medium chain nono- and diglycerides, BHA |

Spray congealing and fluid bed melt granulation are alternative manufacturing techniques to process the molten solution at the elevated temperature to solid particles at room temperature. In spray congealing, solubilized formulations are atomized into fine droplets and transformed into spherical solid particles when the molten droplets are cooled with air in a spray dryer. In fluid bed melt granulation, solubilized formulation is sprayed into a powder bed as atomized molten droplet. Granules consisting of powder carrier and solidified solubilized formulation are produced inside the fluidizing chamber.

5.8.1 *Soft Gelatin Capsule*

Soft gelatin capsules are the most common dosage form used to deliver solubilized formulations. A list of commercial soft gelatin capsules containing solubilized formulations of poorly soluble compounds is presented in Table 5.4.

Manufacturing of soft gelatin capsule consists of the following key steps: gel mass preparation, fill material preparation, encapsulation, drying (primary drying and secondary drying), and finishing. Gel mass for the capsule shell typically contains gelatin, water, plasticizers, opacifier, colorant, preservative, flavor, and sweetener. Gelatin of different bloom strengths can be used to manufacture the soft gelatin capsule shells. Glycerin, sorbitol, and propylene glycol, individually or in combination, are used as the plasticizer for the capsule shell. Selection of plasticizer is based on the compatibility with fill materials and desired properties of the final products (e.g., hardness and appearance). Propylene glycol is a more effective plasticizer than glycerin. However, the use of propylene glycol is limited since its volatiles lead to changes in the mechanical integrity of capsules and too much propylene glycol interferes with the capsule shell sealing process. Glycerin is the most common plasticizer for soft gelatin capsules. However, capsules shell containing too much glycerin can be tacky due to the hygroscopicity of gelatin. Sorbitol is likely to crystallize out of the capsule shells when the capsules are stored at low humidity conditions.

A mixture of glycerin and sorbitol is most commonly used. For the preparation of gel mass, all components are mixed together at room temperature to hydrate the gelatin. The mixture is then processed at high temperature (90°C) under vacuum to form molten gel mass, which is kept at 60°C until the encapsulation. Fill material must be kept below 35°C so that the sealing of capsule is not interfered with by the fill material. Soft gelatin capsules are produced on a rotary die machine, which is fed by two tanks of materials: molten gelatin at 60–65°C and fill material at a temperature less than 35°C. Molten gelatin flows onto the surface of two separate drums, where flat, solid ribbons of gelatin are formed. Liquid fill material is injected into the space between two ribbons. The injection of the liquid formulation forces the gelatin to expand into die pockets. As the ribbons continue to pass the heated wedge and pressed between the die rolls, capsule halves are sealed together by the application of heat and pressure (Jimerson 1986). A fill-weight accuracy of $\pm 4\%$ can be easily achieved with rotary die process. Soft gelatin capsules coming off the encapsulation machine go through primary and secondary drying processes to remove the excess water in the gelatin shell. Water content of the shell is high in order to facilitate the encapsulation process. In primary drying, water leaves the shell and evaporates into atmosphere. At the same time, water could also migrate into the fill materials. As the drying process proceeds, the excess water partitions back out of the fill materials into the capsule shell and out into the atmosphere. Water migration during drying is illustrated in Fig. 5.5 (Gullapalli 2010). It is important to understand the effect of this dynamic change in water content on the physical and chemical stability of capsule shell and fill materials. Migration of water into the fill materials could cause the precipitation of solubilized drug. Serajuddin et al. (1986) studied the effect of water migration on the stability of encapsulated drug solution in PEG 400. After the equilibration of capsule at ambient condition, 6.3% water was present in drug solution in PEG400. This reduced the solubility by 45%, in resulting drug crystallization. When Gelucire 4414 was incorporated into PEG400 formulation, water migration was hindered and drug crystallization was not observed during 3 months of observation. Besides the migration of water, migration of other small molecules such as drug itself, plasticizer in capsule shell, and co-solvent in fill material can also take place during the primary and secondary drying processes. Migration of these excipients is accelerated by the high shell water content and high product temperature during drying.

The biggest challenges with soft gelatin capsules are identifying means to prevent or minimize the chemical and the physical interactions between the capsule shell and fill material. Development of the shell formulation is as critical as the development of fill formulation. The chemical stability of drug solubilized in lipid formulation must be evaluated by mixing the formulation with a small amount of water and representative empty soft capsule shell while monitoring the stability of drug in the mixture. The presence of aldehyde in the fill material can result in cross-linking of gelatin, which would reduce the drug release rate during the shelf life of the product. Furfural generated at the elevated temperature from rayon coil, a common packaging material, is also known to cross-link gelatin. If drug contains aldehyde group, incorporation of succinic acid in the gelatin shell could be used to

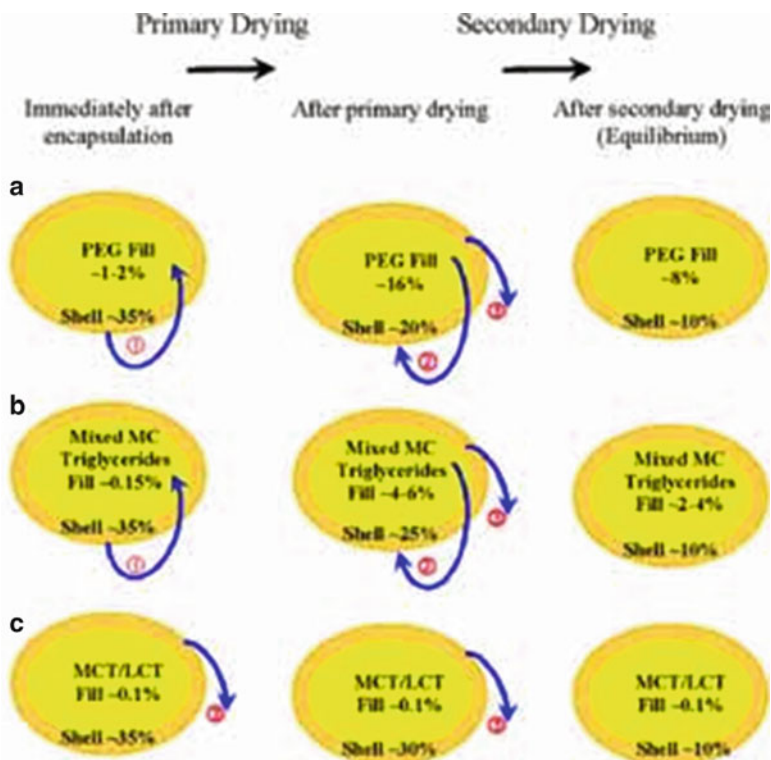

Fig. 5.5 Dynamics of water migration during Softgel Drying Process Water migration patterns during drying of a softgel product containing a typical (a) PEG 400 fill formulation; (b) mixed medium chain mono-, di-, and triglycerides fill formulation with or without an added surfactant(s); and (c) medium chain triglycerides (MCT) or long chain triglycerides (LCT) fill formulation. Yellow inner core represents fill formulation and brown exterior represents gelatin shell. Numerical values represent approximate percent water content, w/w. (1) Water migration from shell to fill, (2) water migration from fill to shell, and (3) water migration from shell to environment

prevent cross-linking. Succinylated gelatin is not commonly used for pharmaceutical products but has been widely used in nutraceutical products. Aldehydes can also be generated from auto-oxidative degradation of excipients containing polyoxyethylene groups, such as PEG, Poloxamer, Gelucire, and the like (Bindra and Stella 1994). When these excipients are present in fill material for soft gelatin capsules, incorporation of antioxidants in the formulation is necessary. BHT, BHA, and vitamin E are commonly used antioxidants in soft gelatin capsules.

When the fill material is lipid-based drug solution, studies must be conducted to determine the solubility of poorly soluble drug in lipid vehicle that is in equilibrium with water. The study is performed to simulate the scenario of the migration and retention water from capsule shell to fill material inside soft gelatin capsule. Solutions of poorly soluble drugs in lipid vehicle at several different concentrations are prepared.

Each solution is then mixed with small amount of water. When the mixtures reach the equilibrium, the highest concentration at which no precipitation is observed is considered to be the solubility of drug in “soft gelatin compatible vehicle.”

As discussed previously, hydrophilic excipients such as low-molecular-weight PEG, ethanol, and propylene glycol can diffuse into the capsule shell easily, especially during the drying stage. Plasticizer in the shell also tends to migrate into hydrophilic fill materials. The amount of these hydrophilic excipients should be kept at a minimum level. Water content in the fill material must be kept below 5%. Several formulation strategies can be applied to achieve a stable product containing hydrophilic fill materials. High-bloom, low-viscosity gelatin is better suited to encapsulate hydrophilic material, since the initial water content in this type of gelatin shell is lower and the process for drying this type of gelatin shell is much shorter. Partially replacing glycerol with sorbitol as the plasticizer in the capsule shell, and adding small amount of glycerol and sorbitol into the fill material can minimize the migration of plasticizers from the shell to the fill material (Werner 1988). Diffusivity of PEG decreases with increased molecular weight. Therefore, better stability can be achieved by using liquid PEG with higher molecular-weight (with a minimum molar mass of 400).

Migration of drug into the capsule shell must also be monitored for soft gelatin capsules. In general, drug migration is less a concern for solubilized formulations containing poorly water-soluble drugs, since these hydrophobic drugs have low affinity for hydrophilic capsule shells. Armstrong et al. (1984) investigated the drug migration from the fill material (drug solution in isopropyl myristate) into capsule. No correlation was found between the extent of drug migration and drug solubility in isopropyl myristate. However, there is a direct correlation between the extent of drug migration and drug solubility in aqueous medium. Most of the drug migration took place during the primary drying (rotating basket). Smaller degree of migration took place during the secondary drying (tray drying). There was no additional drug migration in the first 6 months of storage following the manufacturing.

5.8.2 *Hard Gelatin Capsules*

Over the last decade, encapsulating liquid and semi-solid compositions in hard gelatin capsules is becoming more accepted. Several hard gelatin capsules containing solubilized compositions of poorly soluble drugs have been commercialized. Due to the concern over the leakage of liquid formulation, the fill material for hard gelatin capsules is generally semi-solid or solid at ambient condition. Hard gelatin capsules containing ibuprofen solubilized in Gelucire 44/14 is marked in Europe under brand name Solufen®. Hard gelatin capsule containing fenofibrate solubilized in Gelucire 44/14 and PEG 20000 mixture is marked in Europe as Fenogal®. The Manufacturing process for hard gelatin capsules is much simpler than that for soft gelatin capsules. A comparison between the soft gelatin capsule and hard gelatin capsule manufacturing processes is presented in Table 5.5.

Table 5.5 Comparison between soft gelatin capsule and hard gelatin capsules

| | Soft gelatin capsules | Hard gelatin capsules |
|---|--|---|
| Properties of fill materials | Liquid, liquid suspension No concern over the leakage of low viscosity fill materials Compatible with hydrophobic fill materials; Compatible with formulations containing low level of hygroscopic excipients such as liquid PEG Maximum temperature of fill materials: 40°C Major concern | Liquid, liquid suspension, semi-solid, solid with low melting point Leakage of low viscosity fill materials is a concern. Compatible with hydrophobic fill materials; Hygroscopic excipients such as liquid PEG can only be present at a much lower level Maximum temperature of fill materials: 70°C Less a concern, especially when the fill material is semi-solid or solid at storage conditions 40–60% relative humidity is preferred |
| Interaction between capsule shell & fill contents | | |
| Manufacturing environment | Strict requirement on the manufacturing environment; 20–30% relative humidity | |
| Manufacturing process | Capsule shells are made during encapsulation. Manufacturing process is complex. Only a few companies possess acknowledge, equipment & facility. | Capsule shells are prefabricated for encapsulation. Manufacturing process is simple. |
| Postencapsulation | Lengthy secondary drying (could take several days) | Banding or sealing right after the encapsulation followed with quick drying |

Manufacturing of hard gelatin capsules consists of encapsulation and banding processes. With the installation of a liquid dosator, capsule machine used for filling powder and granule can be easily modified to fill the liquid formulation. The Composition of hard gelatin capsules for encapsulating liquid and semisolid formulations is the same as that of hard gelatin capsules for encapsulating powder and granules. Capsule shells contain gelatin as the structural material, colorant, and TiO_2 as the opacifier. Capsule shell manufacturers have designed gelatin capsules where the body fits tightly into the cap and functions as the primary seal barrier in order to prevent the leakage of liquid formulations prior to sealing or banding operation. In the banding operation, concentrated gelatin solution is applied to the junction of body and cap to form a seal when the gelatin solution dries up. The gelatin banding process is time consuming and labor intensive. Capsugel Inc. has invented and commercialized LEMS™ (Liquid Encapsulation by Micro-Spray) banding technology where a water and ethanol (1:1 ratio) mixture is sprayed into the junction of the body and cap (Cole et al. 2008). As a result of the capillary effect, the solution is drawn into the gap between the body and cap. The gelatin then melts to fuse the cap and body together. A gentle heat is required to remove the residual water/ethanol solution. Compared with traditional capsule banding, LEMS™ sealing operation is more efficient and easier to control.

Cade et al. (1986) used vitamin A palmitate, peanut oil, and vitamin E as the model compounds to determine the fill-weight uniformity of liquid-filled hard gelatin capsules on a commercial-scale machine. The relative standard deviation of the fill weight was less than 0.5% at target fill weight of 400 mg. The consistency of the liquid encapsulation process is highly dependent on the rheology of the fill materials. The viscosity of the fill material should be kept between 100 and 1,000 cP. If the viscosity is too low, the fill material might splash in a high-speed filling process and the fill material might seep out into the overlapping area between the body and cap. If the viscosity is too high, the fill material might string at the dosing tip during manufacturing. Splashing, seeping out, and stringing due to improper viscosity of the fill materials could “contaminate” the overlapping area between the body and cap and, therefore, prevent the proper seal of the capsules (Cole et al. 2008). Splashing and seeping can be overcome by incorporating viscosity enhancers. Polymers such as povidone and hydroxypropyl cellulose, high-melting-point excipients such as hydrogenated oils, and suspending agents such as silicon dioxide and colloidal clays can be used to increase the viscosity of the fill materials.

For high-molecular weight PEG-based formulations, the cooling of fill material inside the capsule could have an effect on drug release properties of the finished product. PEG is a semi-crystalline excipients and its crystallization is dependent on the cooling condition. Higher amorphous content due to the fast cooling could result in faster drug release. Higher amorphous content of PEG as the result of flash cooling was identified to be the contributing factor for the faster release from PEG matrices (McGinity et al. 1984). Chatham (1987) used PEG as the model to demonstrate the effect of processing temperature of fill material, the duration of holding the fill material in the molten state, and the cooling rate following encapsulation on crystallization of PEG inside gelatin capsule and potentially the drug release rate

from the capsule. Fast cooling of PEG-based dispersions has also been reported to result in faster drug release.

To be encapsulated in hard gelatin capsules, the formulation must be chemically and physically compatible with gelatin shell. Chemically, cross-linking of gelatin by aldehydes in the formulation is known to cause the decrease in drug dissolution rate and decrease in bioavailability. For the formulation to be physically compatible with hard gelatin capsules, migration of the water between the fill contents and capsule shells must be inhibited or minimized. The water content of empty gelatin capsules are 14–16%. If too much water migrates from capsule shell into the fill material, the shell becomes brittle and is likely to fracture during shipping and handling. As in soft gelatin capsule, the migration of water into the fill material could also cause solubilized drug to precipitate in hard gelatin capsule. If too much water migrates from the fill material to the shell, the shell becomes soft and loses its physical integrity. Cade and Madit et al. (1996) developed a testing procedure to determine the miscibility between the fill material and hard gelatin capsules. Filled capsules are stored at various relative humidity conditions (ranging from 2.5 to 60% relative humidity) and the weight change in the shell is monitored for 2 weeks. The acceptable weight change is $\pm 2\%$. Kuentz and Rothlisberger (2002) used texture analysis as a nondestructive test for hard gelatin capsules containing liquid formulations to investigate the effect of water migration on the mechanical properties of capsule shell. It was concluded that small amounts of water are often required in the fill material to inhibit water migration between the capsule shell and fill material.

Formulations containing high level of hydrophilic co-solvents such as ethanol, glycerin, propylene glycol, and low-molecular-weight PEG are not compatible with hard shell capsules. The capsules become brittle and break easily when these hydrophilic solubilizers pull the water from the capsules during the storage. These formulations are generally encapsulated in soft gelatin capsules. High-molecular weight PEGs and Poloxamer are an exception. They are compatible with hard shell capsules since they form solid plugs inside the capsules at ambient conditions. Incorporation of antioxidant in the formulation has been demonstrated to further improve the stability of hard gelatin capsule shell containing PEG matrices (Stain and Bindar 2007). Lipophilic excipients such as super-refined oils and tri-glycerides of fatty acids are compatible with hard gelatin capsules. A comprehensive summary of excipients compatibility of hard gelatin capsule shell is presented in Table 5.6.

Most hydrophilic solubilized formulations for hard gelatin capsules are based on solid PEG (MW \geq 4,000) and Poloxamer. These formulations are semi-solids or solids at the ambient temperature and have low melting points ($<60^\circ\text{C}$). They can be filled into hard gelatin capsules as molten liquids. When cooled to ambient temperature, the molten formulations transform into a semi-solid or solid plug inside the capsules. Hard gelatin capsules maintain physical integrity, as long as the temperature of fill materials is lower than 70°C . PEG-based solubilized nifedipine formulation is commercialized as hard gelatin capsules in Europe under the trade name Aprical[®]. The formulation matrix is a mixture of low-molecular-weight PEG and high-molecular-weight PEG (Hohne et al. 1990). Nifedipine is highly soluble in both the liquid low-molecular weight PEG and the melt of high-molecular weight

Table 5.6 List of excipients compatible with hard gelatin capsule shell

| Excipient category | Excipient list | | |
|-------------------------------|--|----------------|------------------|
| Long-chain triglycerides | Soybean oil | Sesame oil | Peanut oil |
| | Olive oil | Cottonseed oil | Hydrogenated oil |
| | Corn oil | Castor oil | Safflower oil |
| Medium-chain tri-glycerides | Medium chain triglyceride (Miglyol 810, Miglyol 812, Captex 300, Captex 355, Labrafac CC) | | |
| Fatty acid and related esters | Oleic acid | Lauric acid | |
| | Propylene glycol ester (Capryol, Lauroglycol) | | |
| | Polyglycerol ester (Plurol Oleique) | | |
| Surfactants | Polyoxyl-40 hydrogenated castor oil (Cremophore) | | |

PEG. Compared against the traditional tablet containing micronized nifedipine, nifedipine solution in PEG 200 has improved bioavailability, higher C_{max} , and shorter T_{max} . However, liquid PEG is not compatible with hard gelatin capsule shell. When high-molecular-weight PEG is used, nifedipine dissolves easily in molten PEG. However, nifedipine crystallizes out of the formulation when molten PEG solidifies at ambient conditions. Aprical[®] is based on the mixture of liquid PEG 300 and solid PEG 6000. With the proper PEG 300 and PEG 6000 ratio, the formulation is compatible with hard gelatin capsule and no crystallization of nifedipine is observed during the storage.

5.8.3 Spray Congealing

Spray-congealing process, also known as spray cooling or prilling process, is commonly used in food and chemical industry to convert a pool of molten liquid into solids spheres. The operation principles and processing parameters for the spray-congealing process is discussed by Killeen (1993). The same basic equipment used for spray congealing is also used for spray drying. Unlike spray drying, spray congealing is a solvent or water-free process. In spray-congealing process, cooling air is passed through the chamber to remove the thermal energy from the atomized droplets. In spray-drying processes, hot air is passed through the chamber to flash off the solvent or water. To undergo spray congealing, solid material is melted and transformed into a low-viscosity liquid. The molten liquid is then atomized into molten droplets inside a chamber with cooling air passing through. The residence time inside

the cooling chamber ranges from a few seconds to 1 minute. The molten droplets cool and solidify into spherical particles inside the cooling chamber. For both spray-drying and spray-congealing processes, air cyclone is used to convey the particles out of the cooling chamber into a collector. The spray-congealed material can then be compressed along with other excipients into tablets or filled into capsules.

The most critical processing steps in spray congealing are atomization and cooling. Pneumatic atomizer (two-fluid nozzle) and rotary atomizer (centrifugational atomizer) are used to disperse the melt into fine droplets. In pneumatic atomizer, the kinetic energy from the compressed atomization air breaks the liquid feed into fine droplets. The medium particle size of the droplets is typically in the range of 50–300 μm . The higher the atomization air volume to liquid mass rate ratio, the smaller the droplet size. The lower the viscosity of the feed material (higher feed material temperature), the smaller the droplet size. Generally speaking, larger particles can be achieved when the process is scaled up in larger size equipment. Longer residence time inside the cooling chamber of larger sprayers allows bigger droplets to cool and solidify sufficiently before they are collected. When a rotary atomizer is used, the molten liquid, introduced to the center of a rotating wheel, is accelerated to the wheel edge by centrifugational forces from the rotating wheel. When the liquid is discharged at the edge of the wheel, it breaks into fine droplets. The advantages of rotary atomizer over pneumatic atomizer are: (1) rotary atomizer can handle materials of higher viscosity; (2) larger particles can be produced with rotary atomizer; and (3) particle size is more uniform. In rotary atomization processes, droplet diameter is proportional to liquid feed rate (power of 0.2) and inversely proportional to the disk speed (Mackaplow et al. 2006).

Spray congealing has been successfully applied in micro-encapsulation, drug stability enhancement, taste masking, sustained release delivery, and excipients manufacturing. Yajima et al. (1999) demonstrated the effectiveness of taste masking of spray-congealed clarithromycin wax matrix consisting of glycerol monostearate and Eudragit E. Spray congealing of hydrophobic matrix comprising fatty acid, wax, glyceride, and emulsifier for masking the taste of pseudoephedrine HCl, dextromethorphan, and cholestyramine is disclosed by Sharma et al. (1989). Preparation of controlled release of Verapamil hydrochloride wax microparticles via spray congealing has been reported by Passerini et al. (2003). Microcrystalline wax and stearyl alcohol were investigated as the sustained release agents. Verapamil hydrochloride maintained its crystallinity in spray-congealed microparticles. At 10% drug loading, the drug was released over 8 h period. Compritol® 888 ATO, a free flowing powder of glycerol behenate supplied by Gattefosse, is manufactured via the spray-congealing process. Preparation of solid solutions of mannitol with various sugars for use as suspending agents or carrier for drug formulations via spray-congealing process is disclosed in a patent (Scott 1967).

Spray-congealed particles can be blended with excipients and compressed into tablets or filled directly into the capsules. Juppo (2004) applied a spray-congealing technique to transform the solubilized formulation of felodipine into a multiparticulate-modified release dosage form with improved drug absorption. The molten drug solution maintained at 110°C was atomized with a pneumatic nozzle using hot

atomizing air at 400°C and a pressure of 7 bar. Spray-congealed particles were 50–100 μm in the diameter and 0.95 in roundness.

Molten formulation is flash-cooled in spray-congealing process. Therefore, polymorphic transformation of the carrier excipients must be closely monitored. If necessary, curing of the spray-congealed particles under elevated temperature can be applied to allow the conversion to more stable form. Emas and Nyqvist (2000) studied the thermodynamic changes in the thermal properties of spray-congealed carnauba wax microspheres with microcalorimeter. Annealing procedures were developed to accelerate the thermodynamic transition during the storage. Glycerol tripalmitate crystallized predominately in metastable α form following spray congealing. The metastable form gradually converted back to stable β form upon storage. The conversion was accelerated when the spray-congealed material was heated slightly above the melting point of α form.

5.8.4 Fluidized Bed Melt Granulation

Fluidized bed processes have been used for drying, granulating, and coating pharmaceutical products. For solubilized formulation with low melting point, fluidized bed processes could be used to incorporate the formulation into a powder substrate to produce free flowing granules. Fenoglide[®] is a commercial product containing solubilized composition of fenofibrate. The product is manufactured with a melt granulation process, where a solution of fenofibrate in PEG 6000 and Poloxamer 188 was sprayed onto the fluidized lactose monohydrate powder bed (Holm et al. 2007).

Fluid bed granulator can be modified to perform melt granulation. In fluidized bed melt granulation, heating of both the liquid feed line and atomization air is required to prevent solidification of the feed material in the line and to ensure proper atomization of the molten formulation. The spray nozzle needs to be properly positioned so that the atomized formulation is in the molten state in the agglomeration zone of the fluidized bed. To achieve uniform and gradual growth of the melt granules, it is critical to maintain the product bed temperature below the melting point of the solubilized formulation. This would allow the growth of the granules to take place in the agglomeration zone only. If the solubilized formulation is predominately in its molten state in fluidized bed, that could potentially lead to the collapse of the bed.

For the manufacturing of Fenoglide[®], drug solution in PEG and Poloxamer 188 is kept at about 80°C. The temperature of substrate was found to be the critical processing parameter. In several enabling examples disclosed in the patent, the atomization air was kept at 100°C and the inlet air was at ambient temperature (20–25°C) for the controlled agglomeration. When the inlet air temperature was heated to 85°C, the geometric weight mean diameter grew to 980 μm even at 25% solubilized solution loading. In contrast, geometric weight mean diameter grew only to 450 μm even at 60% solubilized solution loading under the controlled agglomeration conditions.

Granules containing the solubilized formulation were blended with Avicel PH200 and magnesium stearate, and compressed into tablets. In the animal PK study,

the percent drug absorbed from the tablets was at least 50% higher than that from nanosuspension and microemulsion. It was also found that the higher the ratio between the solubilizing agent and drug, the greater the absorption.

5.8.5 *Powered Solution Technology*

Powered solution technology, also known as Lquisolid technology, is to absorb drug solution onto porous solid excipients to prepare a flowable and compressible powder. The powder can be further processed into a capsule or tablet dosage forms. To date, there has been no commercial success with this type of formulation. A mathematical model has been established for formulating powdered solution composition. The model can be used to calculate the optimum quantity of carrier excipient needed to prepare powder with desired flow and compaction properties (Spireas et al. 1992). Even though a solid dosage form is developed, drug remains in solubilized liquid state. Colloidal SiO₂, microcrystalline cellulose and natural clays are commonly used solid carrier. Large surface of the solid carrier and drug being at solubilized state are two contributing factors for fast drug release and improved absorption. Drug could precipitate from the absorbed solution as the result of moisture absorption during the storage.

Sheth and Jarowski (1990) used powdered solution to improve the drug-release properties of polythiazide tablets. Solution of polythiazide in PEG 400 (60 mg/ml) was triturated with amorphous silica. The liquid carrying powder mass was then passed through a 40-mesh screen and blended with microcrystalline cellulose. The resulting free-flowing powder was compressed into tablet. Almost 90% drug was released at 5 min. In contrast, less than 20% drug was released from directly compressed tablets containing drug and microcrystalline cellulose. Drug release from polythiazide lquisolid tablets is a function of the ratio between drug solution, silica and microcrystalline cellulose, the duration of mixing, and the order of mixing. The tablets were physically and chemically stable when stored at 40°C and 75% relative humidity.

Hydrochlorothiazide lquisolid tablets were prepared using PEG200 as the solubilizer and Avicel® PH 101, and Aerosil and light magnesium carbonate as the carriers (Khaled et al. 2001). The absolute bioavailability of lquisolid tablets was 15% higher than that of commercial tablets. Inclusion of certain water-soluble additives such as PVP in the drug solution as crystallization inhibitor can further enhance the bioavailability of the solubilized drug in Lquisolid tablets (Spireas 2002).

5.8.6 *Summary*

Co-solvent-based, PEG-based, and lipid-based solubilization formulations have been demonstrated to be viable delivery systems for enhancing bioavailability of

poorly water-soluble drugs. Drug bioavailability is improved due to fast dissolution rate and transient supersaturation of drug. Certain lipid excipients are also known to improve the absorption by enhancing lymphatic inhibition of P-glycoprotein-mediated efflux and by inhibition of CYP3A metabolism. Limited by their drug-loading capacity, PEG-based and lipid-based solubilized formulations are more suited for delivering low-dose compounds. Soft gelatin encapsulation, hard gelatin encapsulation, spray congealing, fluid bed melt granulation, and absorption into solid carriers are commonly used techniques used to prepare the solid dosage forms containing solubilized formulations. Physical stability of the solubilized formulation should be closely monitored. Formulation composition, manufacturing process, and packaging configuration must be properly selected so that poorly soluble drugs remain solubilized during the manufacturing and on the shelf.

Method Capsule 1

Preformulation Support of Solubilized Formulations

Based on the method reported by Desai and Park (2004)

Objective

- To determine the solubility of valdecoxib in a variety of solid carriers, co-solvents, and surfactants.

Equipment and Reagents

- Valdecoxib
- Polyethylene Glycol 4000, 6000, 8000
- Urea
- Mannitol
- Tween 20, Tween 80
- Sodium lauryl sulfate
- Glycerol
- Ethanol
- Methanol
- Purified water

Method

- Solubility studies with 1, 2, 5, 10% wt/vol for carrier–water mixtures.
- Solubility studies with 10, 20, 30, 40, 50% wt/vol for co-solvent–water mixtures.
- Solubility studies with 0.25, 0.50, 0.75, 1.0% wt/vol for surfactant–water mixtures.
- Powder X-ray diffraction and scanning electron microscopy for characterization of valdecoxib drug substance.

Results

- The solubility of valdecoxib increased up to 8-, 7-, 6.7-, and 4.2-fold for PEG 4000, PEG 6000, PEG 8000, and urea, respectively. Mannitol provided no solubility benefit.
- Co-solvent systems through 50% wt/vol showed a rank-order increase of solubility such that ethanol>methanol>glycerol which was due to the greater polarity of the mixed solvent system.
- Anionic surfactant (sodium lauryl sulfate) provided greater solubility enhancement than nonionic surfactants (Tween) and was associated with the micelle interaction between the surfactant and valdecoxib.

**Method Capsule 2
Miniaturized and Automated Screening of Liquid
and Semi-solid Formulations**

Based on the method reported by Mansky et al. (2007)

Objective

- To apply a material sparing and efficient screening method to identify liquid and semi-solid formulations.

Equipment and Reagents

- JNJ-25894934, JNJ-3026582
- Gelucire® 44/14
- Hydroxypropyl- β -cyclodextrin
- Tween 20, Tween 80
- Volpo 10
- Capmul® MCM, PG8
- Captex 200
- Maisine 35-1
- Myvacet® 9-45
- Oleic acid
- Capric acid
- Vitamin E TPGS
- TECAN Genesis Workstation (96 Well Model)

Method

- Compound and excipient stock solutions were prepared, metered, and dried to using the TECAN system into 96 well plates.
- Samples were aged as necessary by protocol.
- Microplate dissolution was performed and concentration profiles assessed by HPLC.

Results

- Testing was successfully performed using drug levels as small as 50 μg per well, allowing for multiple formulation evaluation within a material sparing design.
- Binary drug–excipient evaluation at multiple drug loadings revealed that JNJ-25894943 and JNJ-3026582 were solubilized at up to 100 mg/g by Vitamin E TPGS and Incrocas 35, with Vitamin E TPGS being the most effective stabilizer over extended durations for both compounds.
- Kinetic solubility data generated by the high-throughput methodology was highly correlated with conventional solubility screening.

Method Capsule 3**Evaluating Lipid Formulation In Vitro and Ex Vivo**

Based on the method reported by Dahan and Hoffman (2007)

Objective

- Investigate the impact of different lipid-based formulations on in vitro solubilization and intestinal ex vivo permeability.

Equipment and Reagents

- Dexamethasone, griseofulvin
- Peanut oil (long-chain triglyceride)
- Triacetin (short-chain triglyceride)
- Taurocholic acid
- Pancreatin
- L- α -phosphatidylcholine
- Tris maleate
- Calcium chloride

Method

- Simulated in vitro lypolysis performed using an Using diffusion cell and ultracentrifugation to separate drug phases that are available for absorption.
- Permeation was assessed using an ex vivo model by means of intestinal segments of male Wistar rats.
- In vivo oral bioavailability of formulations was assessed in male Wistar rats at a dose of 5 mg/kg with plasma concentration assessed by high-performance liquid chromatography.

Results

- In vitro lypolysis showed a correlation of improved performance for griseofulvin formulations with increasing triglyceride chain length while no major improvement was observed for dexamethasone.

- Ex vivo results showed that short-chain triglycerides improved permeability for dexamethasone and griseofulvin.
- In vivo results were well correlated with in vitro data when comparing rank order identified for each drug-formulation; however, the observed ex vivo permeability enhancement of the short-chain triglyceride was not confirmed in vivo.
- Limited changes of internal porosity were the result of elastic recovery and molecular rearrangement during the dissolution process.

Method Capsule 4

Cross-linking of Soft Gelatin and Hard Gelatin Capsules

Based on the method reported by Meyer et al. (2000)

Objective

- To utilize in vitro analysis to predict bioequivalent and bioinequivalent capsules.

Equipment and Reagents

- Acetaminophen
- Lactose
- Polyethylene Glycol 600, 1000
- Hard Gelatin Capsules, Size 1
- Type B Gelatin, 150 bloom limed-bone gelatin
- Glycerin
- Sorbitol

Method

- Hard gelatin capsules were stressed by filling with lactose containing 20 ppm and 120 ppm of formaldehyde while storing for six days at room temperature and one day at 40°C/75%RH. Capsules were then emptied and manually filled with acetaminophen.
- Soft gelatin capsules were prepared containing 0, 20, and 80 ppm, with a storage period of over 30 weeks at 25°C/60%RH and 40°C/75%RH.
- In vitro dissolution was conducted using USP Apparatus II with 900 mL of simulated gastric fluid containing pepsin at 50 rpm.
- Two separate 24-subject, three-way crossover, bioequivalence studies using three different lots of hard gelatin capsules and three different lots of soft gelatin capsules, all having experienced different levels of stress.

Results

- Hard gelatin capsules exposed to increased levels of formaldehyde failed to meet USP dissolution testing requirements in SGF and water.

- Soft gelatin capsules containing 20 ppm formaldehyde met dissolution requirements; however, higher levels failed to comply with USP specifications after 55 days storage at 40°C/75%RH.
- Oral bioavailability of stressed capsules showed similar AUC when compared to nonstressed product; however, a statistically significant increase in T_{\max} was observed for stressed product due to the cross-linked induced delayed release.

Chapter 6

Injectable Formulations of Poorly Water-Soluble Drugs

Michael P. Boquet and Dawn R. Wagner

Abstract A growing number of new therapeutic molecules are limited by low or erratic bioavailability due to poor water solubility. Because of the clinical demand for new and more efficacious anti-cancer, antiviral, and anti-infective drugs, many of these new drugs must be formulated for injection. Poor water solubility can be addressed by a range of formulation approaches such as pH manipulation, salt formation, and cosolvent and surfactant addition, or by more advanced techniques such as complexation, liposomal encapsulation, or nanosuspension. While remaining focused on drug solubility, issues such as buffering, tonicity, sterility, and drug product stability also must be considered when formulating injectable products. This chapter outlines a formulator's approach toward development of an injectable drug product containing an active ingredient with poor solubility. Marketed injectable products, listings of GRAS excipients, and techniques for enhancing solubility are offered as case studies to assist in the formulation process.

6.1 Introduction

A drug product administered directly into a vein (IV), into the subcutis layer of skin directly below the dermis and epidermis (SC), or into a relaxed muscle (IM) is classified as an injectable. There are other routes of injectable administration for specific indications, but IV, SC, and IM are the most common. Although other routes of drug product administration are often more desired than injection due to patient compliance and less stringent production requirements, injectable formulations

provide critical products to treat patients for a variety of indications. Almost half of the drugs currently administered in hospitals are classified as injectables. In 2006, seven of the top ten best-selling hospital drugs by wholesale acquisition cost were injectable products (Wolters Kluwer 2006). These medications are used to treat a variety of indications including anemia, blood clots, infection, rheumatoid arthritis, and non-Hodgkin's lymphoma. In addition to the many commercial indications treated by injectable products, injectable formulations also support drug product development activities for both injectable and noninjectable dosage forms in preclinical and clinical studies, aiding in the assessment of both toxicity and pharmacokinetics.

A large percentage of drugs that are currently in preclinical and clinical development for injectable administration are considered poorly water soluble. Developing an injectable formulation and drug product for a poorly water-soluble compound can be challenging because there is no one best approach. This chapter provides a guidance for developing a robust injectable product and strategies for improving the solubility and stability of poorly water-soluble drugs for injectable delivery.

6.2 Identifying Product Attributes

It is critical that both desired and acceptable final product attributes and end-user utilization considerations are identified prior to commencing development activities for an injectable product. Within the pharmaceutical industry, the generation of a target product profile (TPP) is a frequently used approach in the “quality by design” methodology for documenting and updating this type of information. A comprehensive TPP will include information such as the intended route of administration, anticipated dose range, dose frequency, dose duration, volume per dose, and drug concentration. An excellent review containing suggested guidance for developing and updating a TPP for injectable products has been provided by Lambert (2010). The TPP, along with regulatory implications and properties of the active pharmaceutical ingredient, will dictate the acceptable characteristics of the injectable product including pH range (buffer and solid-state form selection), isotonicity (tonicity agent and diluent), sterility (manufacture process and container closure system), preservative requirements (unit or multidose), and excipient constraints (concentration and grade).

6.3 Routes of Administration

6.3.1 *Intravenous*

IV administration involves injecting the drug product directly into a vein, typically located within the upper extremities. The injection is usually performed with a sterile needle and syringe or a sterile plastic catheter as part of an IV infusion set. Since the drug product is injected directly into the vein, the drug is immediately bioavailable since there is no need for absorption and permeation through membranes or tissues. This advantage provides a clinician more control over serum concentrations

Table 6.1 Examples of commercial drugs for IV administration

| Molecule/indication | Preparation | Administration |
|--|--|--|
| Dexamethasone sodium phosphate/ anti-inflammatory | none | IV direct injection slowly over 1 to several minutes or by IV infusion |
| Dopamine HCl/correction of hemodynamic imbalances | Concentrated solution must be diluted in D5W; none for premixed solution | IV infusion into a large vein |
| Ondansetron HCl/ antiemetic | None for direct injection; diluted in 50 mL of saline or D5W | IV direct injection slowly over 2–5 min; IV infusion over 15 min |
| Phenytoin sodium/ antiepileptic | none | IV direct injection into large vein |
| Vancomycin HCl/ antibiotic | Reconstitute vial with sterile wfi and dilute with saline or D5W; thaw for frozen premixed infusion solution | Intermittent or continuous IV infusion |
| Warfarin sodium/ anticoagulant | Reconstitute with sterile wfi | Slow IV direct injection 1–2 min into peripheral vein |

and makes IV dosing the preferred route for administration of potent therapeutic agents where ensuring the accuracy of dose is critical. If SC- or IM-injectable formulation causes local irritation or pain at the site, then IV administration is often selected. Only drug products that are solutions or colloidal dispersions (particle size typically $<1\ \mu\text{m}$) may be suitable for IV administration due to the risk of pulmonary embolism resulting from particles $>7\ \mu\text{m}$ (DeLuca and Boylan 1992) and particulate constraints associated with this route of administration.

An IV product can be given either as a bolus dose (a small volume over a short period of time) or as an infusion (a larger dose over longer period of time). A bolus dose is typically less than 10 mL delivered over a few minutes and is used when rapid administration is required or if the drug should not be diluted prior to administration. This method of drug delivery will result in a rapid therapeutic effect, providing an immediate response in emergency treatment situations such as severe hypertension or cardiac arrest. An IV infusion is delivered slowly at a rate of less than 3 mL/min over a number of hours and can be maintained for prolonged periods of time to ensure more accurate serum concentrations. Infusions are used to administer large volumes of fluids to the patient for treating indications such as dehydration or electrolyte imbalance. Drugs such as lidocaine, which need to be delivered continuously for a prolonged therapeutic effect due to their short half-life, are also delivered by infusion (Aschenbrenner and Venable 2009). Examples of some marketed IV products for bolus injection and IV infusion are listed in Table 6.1.

6.3.2 Subcutaneous

SC administration involves injecting a bolus dose of drug product into the layer of skin just below the dermis and epidermis. The drug is injected slowly into the upper

Table 6.2 Examples of commercial drugs for SC and IM administration

| Molecule | Indication | Administration |
|---------------------------------|--------------------------|-------------------------|
| Clindamycin phosphate | Antibiotic | IM injection |
| Epinephrine HCl | Vasoconstrictor | SC or IM injection |
| Hydrocortisone sodium phosphate | Corticosteroid | SC, IM, or IV injection |
| Morphine sulfate | Analgesic | SC, IM, or IV injection |
| Perphenazine | Schizophrenia | Deep IM injection |
| Ranitidine HCl | Stomach ulcer prevention | IM or IV injection |

arm, upper leg, or abdomen with a small thin needle. Once beneath the skin, the drug migrates to the bloodstream from small local blood vessels and is usually effective within 20 min of administration (Cengage 2006); however, the time to therapeutic effect is dependent on the drug and the formulation. For example, Velosulin®BR is an SC-injectable medication for diabetes that achieves therapeutic onset in about 30 min after injection, whereas Depo-subQ Provera 104™ is a sustained release SC product that is administered every 12–14 weeks and reaches steady-state blood levels 3 weeks post injection (Bhalla 2007).

Drugs that can be delivered in a small volume (less than 2 mL) and cannot be delivered orally due to inadequate absorption or degradation within the gastrointestinal tract are often delivered by SC injections. Injectables that are formulated as suspensions are also commonly administered by SC administration because they cannot be delivered by IV injection due to the particle size restrictions. SC-injectable suspensions or oil-based formulations are often developed as drug depot systems for a sustained drug release (Bhalla 2007; Bari 2010). Some commonly used drugs delivered by SC injection include vaccines, insulin, and anticoagulants.

6.3.3 Intramuscular

IM administration involves injecting a bolus dose of medication directly into a muscle. The muscles most commonly used for the delivery of IM injections include the dorsogluteal (buttocks), deltoid (upper arm), ventrogluteal (hip), or the vastus lateralis (thigh). IM injections are delivered in a volume of less than 4 mL and share many of the same characteristics of SC injections including the possibility of delivering suspensions and sustained release medications. The rate of drug absorption into the muscle tissue and subsequently into the surrounding blood stream is typically faster and more predictable than with SC administration (Bhattacharjee and Thoma 2010); however, this is dependent on the site of administration and the properties of the drug and formulation. For some medications, the drug product labeling will specify a muscle for administration. Medications commonly delivered by IM injection include vaccines, hormones, and antibiotics. Table 6.2 includes examples of currently marketed SC and IM products.

6.4 Injectable Formulation Development Challenges

6.4.1 pH

Aside from the aforementioned dosing volume restrictions associated with each route of injectable delivery, there are a number of other challenges and constraints that must be considered when developing formulations for IV, SC, or IM administration. The first formulation property that is often assessed is the pH of the product. Formulations developed for IV and IM injection are typically developed at a pH within the range of 2–12. This range is dependent on the volume, rate of administration, and buffer capacity of the drug product. Ideally, the formulation should be developed as close as possible to physiological pH, about 7.4, and high buffer capacity formulations should be avoided. A small-volume bolus dose that is injected slowly, allowing for rapid dilution in the bloodstream, provides more leniencies within the typical pH range. If a large volume is given as an IV infusion, the acceptable range is reduced to a pH of 2–10 and formulating near the extremes of this range should be avoided. SC injections have more stringent pH requirements, pH 2.7–9.0, due to the increased occurrence of injection site discomfort and irritation near the pH range extremes (Shi et al. 2009). Ultimately, both the solubility and the stability of the compound and the formulation will dictate the most appropriate pH for the final drug product.

6.4.2 Buffer systems

Buffers are often included in a formulation to ensure the intended pH of the solution is maintained within an acceptable range throughout the intended shelf life of the product. Some factors that can cause pH migration in both un-buffered and insufficiently buffered formulations include the formation of degradation products and leaching of materials, such as the primary packaging, that are in contact with the product. A preformulation solubility and stability assessment is performed to identify the pH that provides the desired solubility and sufficient chemical stability based on the degradation rate of the drug. If a solution is desired, the pH that provides the highest level of solubility and lowest rate of degradation is often selected. If a suspension formulation is required, then a lower level of solubility is desired to ensure that the drug does not dissolve into and re-precipitate out from the vehicle (a phenomenon known as Ostwald ripening). A thorough explanation of preformulation solubility and stability assessment has been provided by a number of authors (see Halbert 2009; Tong and Wen 2008). Suspensions will be discussed in greater detail in Sect. 6.6.3.

Common buffer systems used in injectable formulations (Table 6.3) consist of a weak acid with a salt of a weak acid or a weak base with a salt of a weak base. Once the pH is selected, appropriate buffers can be tested for drug solubility, stability, and

Table 6.3 Commonly used buffers in injectable drugs

| Buffer | Effective pH range |
|-----------|--------------------|
| Acetate | 3.7–5.6 |
| Citrate | 2–6.2 |
| Phosphate | 6–8 |
| Succinate | 4–6 |
| Tartrate | 4–5 |
| TRIS | 7–9 |

compatibility based on the effective range of each buffering agent. If the pH range selected allows, multiple buffers are routinely tested because sometimes the buffer may alter the degradation rate of the drug or cause changes in solubility due to a form change of the drug in solution. It is critical that the buffer concentration provides enough buffering capacity to maintain the appropriate pH over the intended shelf life of the product. It is equally important that the buffer concentration is minimized to a level which does not alter blood pH chemistry (IV injections) and decreases the potential for site pain and irritation (IM and SC injection) (Table 6.3).

6.4.3 Tonicity and Biological Implications

The tonicity of a solution is another important consideration when developing an injectable drug product. Two solutions are considered to be isotonic if they exhibit equal osmotic pressure with respect to a particular membrane. If the solution is isotonic with blood plasma for instance, the movement of fluid between the blood cell membrane and the surrounding fluid is maintained. The injection of a hypotonic solution disrupts the balance and exchange of fluid within the membrane, causing the cells to swell; this can lead to cell irritation and may even cause hemolysis, the bursting of blood cells. Injected hypertonic solutions exert a higher osmotic pressure than plasma causing the cells to lose fluid and crenate or shrink. To ensure that cell and fluid homeostasis is maintained, an injectable product should be developed as close to isotonicity with physiological fluids as possible.

Often, it is not possible to develop an injectable formulation that is isotonic with respect to blood. Specific means of preparation or routes of administration of the product can sometimes circumvent possible complications caused by differences in tonicity. It is easier to adjust the tonicity of a low-concentration drug product by either mixing it with a sufficient amount of isotonic diluent such as normal saline or lactated Ringer's solution prior to dosing or incorporating a tonicity modifier into the formulation such as sodium chloride or mannitol. Commonly used tonicity agents and diluents are displayed in Table 6.4. Hypertonic solutions for IV injection can often be tolerated if they are administered in small volumes and at a slow injection rate which provides for rapid dilution with blood in circulation (Troy 2006).

Table 6.4 Commonly used tonicity agents and diluents in injectable drugs

| Tonicity agent | Diluent |
|-----------------|--|
| Dextrose | Sterile water for injection |
| Glycerol | 5% Dextrose for injection |
| Glycine | 0.9% Sodium chloride for injection |
| Lactose | 5% Dextrose in lactated Ringer's injection |
| Mannitol | 5% Dextrose in 0.9% sodium chloride |
| Sodium chloride | 0.45% Sodium chloride |
| Sucrose | 5% Dextrose in 0.45% sodium chloride |
| Trehalose | Lactated Ringer's for injection |

There are a number of methods used to calculate and adjust the tonicity of a solution including the cryoscopic method (freezing-point depression method), sodium-chloride equivalent method, Van't Hoff equation (L_{iso} method), and the White-Vincent method. A number of textbooks provide excellent examples for using these methods to calculate and adjust the tonicity of solutions and should be referred to for a more comprehensive review on this subject (see Alur et al. 2005; Sinko and Troy 2006). In the pharmaceutical industry, the osmolality of most solutions can be quickly measured in the lab using a freezing-point-depression- or vapor-pressure osmometer and then compared to the nominal osmolality of plasma: 275–299 mOsm/kg (Troy 2006). It is important to note that osmolality takes into account both permeable and nonpermeable solute molecules as opposed to tonicity, which only considers nonpermeable solute. Noting that the tonicity is equal to the osmolality less the concentration of solutes that are allowed to freely permeate the cell membrane, one can use this method to acquire an estimation of the potential fluid interactions with plasma. Tonicity will always be equal to or less than osmolality. Solutions that have a relatively high osmolality or include excipients that can alter freezing, such as propylene glycol (PG), and do not contribute to the tonicity of a solution may be iso-osmotic but not isotonic (Troy 2006).

A more definitive method for testing the compatibility of a formulation with blood is an *in vitro* hemolysis test which provides a visual observation of human erythrocytes to determine if the solution causes hemolysis or a volume change in red blood cells. This technique is more predictive in determining the potential of adverse reactions post injection that may result when the solution and biological fluid mix. In addition, *in vivo* tests are performed to determine if there any potential issues associated with treatment including drug precipitation upon injection, phlebitis (cell damage), pain, or injection site irritation. Some drugs, buffers, and excipients are more prone to stimulating this type of reaction than others, and the concentrations, dosing volume, and injection or infusion rate need to be adjusted accordingly. This topic will be discussed in more detail for a number of products in the following sections of this chapter; however, the literature and regulatory precedence specific to the method of administration should be consulted to determine appropriate levels for every ingredient added to the formulation.

6.4.4 Sterility and Endotoxin Requirements

All injectable products must demonstrate sterility according to the microbial limits assay requirements of USP<71>. Some drug products can be terminally sterilized by steam or dry heat if they are not susceptible to degradation caused by exposure to elevated temperatures (121°C) for 15–30 min. Terminal sterilization is the preferred method from both cost and regulatory perspectives; however, a good proportion of drug products cannot be terminally sterilized due to inadequate stability. These products are often processed by sterile filtration, through a 0.22- μ m filter, filled into sterile containers, and sealed under aseptic manufacturing conditions to ensure sterility. Sterility testing has become a hot topic within the pharmaceutical industry and regulatory agencies in recent years due to the increased sensitivity of microbiological assays (Akers et al. 2007). A detailed explanation of sterility testing and its implications for injectable products has been published by Akers et al. (2003).

Endotoxin limits are also placed on injectable products. Endotoxins are part of the outer cell wall of Gram-negative bacteria. After bacterial death and cell lysis, lipopolysaccharide (LPS), an endotoxin, is released from the membrane. At certain levels of exposure, LPS is known to cause a variety of inflammatory responses (Tran and Whitfield 2009). The addition of the active ingredient, excipients, solvents, and other liquids to a formulation can expose the drug product to increasing quantities of endotoxins; therefore, endotoxin dose is product specific. Each component of the formulation, including sterile water for injection, should be scrutinized with respect to the endotoxin level to reduce patient exposure. For nonintrathecal injectable products, the endotoxin limit is 5 EU(endotoxin units)/kg divided by the maximum human dose given per hour. There are a number of approved FDA and USP methods for determining the bacterial endotoxin level of a solution using the Limulus Amebocyte Lysate Test (LAL) including gel-clot, turbidimetric, and colorimetric assays (Birrer et al. 2001).

6.4.5 Particulate Matter

According to USP<788>, “particulate matter in injections and parenteral infusions consists of mobile undissolved particles, other than gas bubbles, unintentionally present in solution.” There are two tests for determining the amount of visible and sub-visible particulate matter in an injectable product: the light obscuration particle count test and the microscopic particle count test. The test establishes particulate count limits per unit volume for the injectable drug product tested and distinguishes particles that are greater than or equal to 10 μ m and 25 μ m. Injectable products that are administered by SC or IM injection only are excluded from these requirements. Dry powder or lyophilized products must be constituted with diluents prior to particulate matter assessment. Some formulations cannot be tested by one or both methods due to high viscosities or sample clarity. In these instances, the solution can be diluted with particulate-free diluent to perform the test.

Table 6.5 Commonly used preservatives in injectable drugs

| Preservative | Concentration (%) |
|-----------------------|-------------------|
| Benzalkonium chloride | 0.01 |
| Benzethonium chloride | 0.01 |
| Benzyl alcohol | 1.0 |
| Chlorobutanol | 0.5 |
| Metacresol | 0.1 |
| Methylparaben | 0.18 |
| Propylparaben | 0.02 |
| Phenol | 0.5 |
| Thimerosal | 0.01 |

6.4.6 Preservatives

If an injectable product is intended for multi-dose applications, the formulation must contain a preservative or demonstrate self-preserving properties that allow it to meet regulatory requirements with regard to antimicrobial effectiveness testing (AET). Formulations that have reduced water activity due to high concentrations of cosolvents, such as PG or glycerin, or contain drugs that are bacteriostatic may not require the addition of preservatives to pass AET requirements (De Spiegeleer et al. 2006). The AET test involves inoculating the drug product with a known concentration of specific microorganisms including certain species of bacteria, yeasts, and molds. In order to pass the requirements of USP<51>and demonstrate sufficient resistance to microbial proliferation, the product must provide a specific log reduction in bacteria and no increase in yeast or molds at specified time points post inoculation. Table 6.5 contains a list of preservatives and the typical concentrations used for preservative efficacy in injectable products. Many factors can affect the performance of preservatives including concentration and pH, as well as circumstances when the preservative is used in combinations with complexing, binding, or encapsulating excipients, which could decrease the amount of “free” preservative in solution. An example where the preservative can become sequestered is with the use of agents that form micelles, including polysorbates and Cremophors, and cyclodextrins (Meyer et al. 2007).

Some preservatives, such as certain types of parabens, have been shown to cause irritation or adverse events at certain concentrations (Soni et al. 2005). Also, there are a number of restrictions on the inclusion of certain preservatives in medications intended for pediatric administration or commercial use in specific countries. It is important to note that like all other excipients, the preservative can have an effect on the stability of the drug product and should be tested to ensure that the shelf-life requirements for the product are maintained. The preservative level in the formulation must be routinely tested on stability because preservative content may change over time due to degradation or interactions with the container closure materials. The minimum concentration of preservative necessary to meet AET requirements at the end of product shelf life should be established as justification for the level included in the drug product (Table 6.5).

6.4.7 *Device and Diluent Compatibility*

During product development, studies must be performed to prove that the drug product is compatible with diluents and devices that come in contact with the product prior to administration. The selection of diluent and volume is product specific and is dependent on the intended drug concentration, dosing regimen, pH, tonicity, and other factors that could alter compatibility with the drug product. Common diluents for injectable products include sterile water for injection (wfi), 0.9% sodium chloride for injection (normal saline), 5% dextrose for injection (D5W), and lactated Ringer's for injection. To test diluent compatibility with a drug product, the drug is diluted to the intended dosing concentration with the vehicle. Physical and chemical stability of the product with respect to time, temperature, and storage (light exposure) is monitored to ensure sufficient stability of the diluted drug over the intended use period. In some instances, drugs added to diluents at specific concentrations precipitate out of the solution due to solubility differences within the vehicle. In many cases, the stability of the product after preparation with diluent is relatively short; therefore, the dose must be administered within the established intended use period. When a drug is administered by IV in a diluent, it is often given in conjunction with other medications through the same IV infusion site. Some drugs may have compatibility interactions when dosed in conjunction with other additives or medications. In most instances, safety and compatibility will need to be established for product labeling purposes.

During preparation and administration, a drug can come in contact with many different materials including filters, needles, syringes, IV infusion bags, IV tubing lines, and other materials that are part of administration sets. All of these materials must be assessed for compatibility with the drug product to ensure product stability. Some drugs or excipients are not compatible with certain types of materials, which can cause concentration differences (adsorption of drug or preservative), pH drift, color change, or introduction of unwanted impurities (leachables or extractables) into the medication. One such example is the drug Prograf[®] (tacrolimus injection), which should only be exposed to containers made of glass or polyethylene. This recommendation is due to leaching of the plasticizer, diethylhexyl phthalate (DEHP), often found in PVC IV bags or tubing lines (Trissel 2002). All of the information gathered during compatibility testing will impact clinical product handling and ultimately commercial labeling.

6.4.8 *Packaging and Manufacturing Considerations*

One of the most important components of a drug product that is often overlooked is the container closure (CC), the primary and secondary packaging that holds the product for the duration of its shelf life. The primary function of the CC is to protect the drug product throughout its lifecycle from manufacture, to shipping, and finally during the in-use period for administration. Stability studies with the drug in the packaging must be conducted to determine if there are any compatibility issues with the

formulation and to ensure that the stability requirements for the product are maintained even at the end of the shelf life. These studies should be done early in the development process to identify any potential issues that may result including binding of the drug or preservative to the container, glass catalyzed hydrolysis, or pH drift. Chelating agents, which are often included in formulations to improve stability, can withdraw metal ions from glass, causing complications (Ernsberger 1959). Leachables may also be extracted by the formulation from contact material such as stoppers or plastics. Packaging component manufacturers offer a number of material choices including specific glass types, plastics, films, or coatings to minimize product interactions with the container closure. For injectable product applications, packaging components can include vials, stoppers, bottles, caps, seals, syringes, infusion bags, and cartons. Some of these options have been discussed by Akers et al. (2007).

The packaging system must adhere to particulate and sterility requirements for injectable products. CC integrity tests are performed to validate that there is no leakage from the packaging, ensuring that the sterility is not compromised. CC seal integrity is also important if the drug product is sensitive to oxidation and requires an inert headspace for stability. A number of these tests have been explained in detail in Remington: The Science and Practice of Pharmacy (Troy 2006). If a drug is light sensitive, the product can be protected from ultraviolet light with either an amber glass vial or the outer carton, depending on the degree of sensitivity. Ultimately, the selection of a proper CC is dependent on the type of product (lyophilized, solution, or powder for constitution), the compatibility of the material with the product, how the product will be sterilized (aseptic fill or terminal sterilization), and how the product will be administered (small- or large-volume injectable for single- or multi-use). It is important to recognize that some countries have restrictions on the use of specific materials, such as PVC, in contact with products for IV administration, which poses a potential hazard due to phthalate leaching (Food and Drug Administration 2011).

During manufacture, the drug product may contact a number of materials including tubing, filters, compounding vessels, and filling needles. Compatibility studies must demonstrate that the manufacture process does not alter the drug product with respect to its release specifications. Some liquid formulations are not compatible with specific types of stainless steel or welds used in compounding vessels and exposure to this material can cause color change or increased degradant formation. During filling and filtration, any flow stoppage that may increase the residence time of the formulation in tubing or filters can cause potency loss due to sorption. It is common practice to saturate any lines or filters with the drug product and flush the line with sufficient volume prior to initiating product filling to ensure proper potency.

6.5 Vehicle Selection and Solubilization

Preformulation efforts to develop an injectable formulation are centered on characterizing the solubility and physical/chemical stability of the drug. In some cases, the intrinsic solubility of the drug is acceptable for development and a simple formulation can be developed using an aqueous vehicle to dissolve the drug. This is not the

case for poorly water-soluble compounds which may require either aqueous, non-aqueous, or cosolvent vehicles that may also include specialized excipients or processing methods. The formulation scientist must explore all of the known techniques for improving solubility and stability while ensuring that the development process is efficient from both a time and cost perspective. The goal is to make a formulation as simple as possible that meets all product and regulatory requirements as well as clinical and commercial end-user utilization considerations.

6.5.1 *pH Adjustment*

The first technique that is explored for increasing the solubility of a molecule is adjusting the pH of the solvent. This technique works for many compounds that can be ionized because this species has a higher aqueous solubility than those that are neutral or unionized. When the pH is at the pK_a , an equal amount of the ionized and unionized form exists. To increase the solubility of weak acids by 10-fold, the pH must be 1 pH unit above the basic pK_a ; for weak bases, the pH must be 1 pH unit below its basic pK_a . For every additional pH unit away from the pK_a , there is an additional 10-fold change in the solubility. As previously discussed at the beginning of this chapter, the pH range of interest for any solubility study should be limited to the acceptable range for the specific route of the injectable. The preferred acid and base for titration to lower or increase the pH of a solution are HCl and NaOH, respectively.

Because it is difficult to control the final solution pH, it can be tedious to generate an accurate and complete pH-solubility profile without the use of a buffered solution. However, a buffer may not be required if the compound and its pK_a provide sufficient buffering in the selected pH range. Buffer solutions, such as citrate (pH 2–6) or phosphate (pH 6–8), that are effective in the pH range for injectable products are prepared at a specific pH and constant ionic strength. These solutions can be mixed in appropriate concentrations to prepare solutions with pHs between 3 and 9 for solubility and stability assessment.

An example of a solution formulation using pH adjustment to improve solubility and stability is Pentothal® (thiopental sodium for injection), which is a thiobarbiturate. The aqueous solubility of thiopental sodium (pK_a of 7.6) is very low at neutral pH (McLeish 1992). Anhydrous sodium carbonate at 60 mg/g of thiopental sodium is used to solubilize the drug by adjusting the pH to 10–11 in the formulation, which is a sterile hygroscopic powder. Pentothal® is reconstituted with any of the recommended diluents and slowly infused intravenously. The product needs to be sealed so as to not take on carbon dioxide, which can react with water, lower the pH, and cause the insoluble form of thiopental to precipitate (Trissel 2002).

6.5.2 *Salt Formation*

As was discussed earlier in this chapter, every buffer can react differently with the compound, often effecting solubility or degradation reaction kinetics. If the solubility

is considerably less at a particular pH with a specific buffer than with water alone, then the compound may have changed to an insoluble/less soluble salt form, formed polymorphs, or is experiencing a common-ion effect if another salt in solution has the same ion present. If the solubility is increased considerably at a specific pH, it is likely the drug converted to a more soluble salt in solution.

The active ingredient can often be supplied as a free acid/base form or as the salt form of the acid or base, which usually has a higher solubility. If the salt form of the active ingredient is not available, an in situ salt can be formed in solution by the presence of counter ions under the right conditions and pH. Typically, a 2 pH unit difference between the pK_a of the acid and base is necessary to convert to the salt form (Kerns and Di 2008). HCl and NaOH are commonly used pH modifiers for basic and acidic molecules, respectively; however, the salts that they form with a compound are often not the most soluble or stable. A few of the most common counter ions for acidic drugs are sodium, calcium, and potassium and for basic drugs, hydrochloride, mesylate, sulfate, citrate, and hydrobromide. It is common to screen a number of salt forms to identify the most promising from a solubility and stability perspective. At equilibrium, it is important to isolate, identify, and characterize the solid-state properties of the most promising salt forms. Determination of crystallinity, polymorphism, and stability is often accomplished by methods such as X-ray powder diffraction (XRPD) and differential scanning calorimetry (DSC). An excellent review of how salt formation can be used to improve drug solubility has been provided by Serajuddin (2007).

6.5.3 *Cosolvents*

If pH adjustment, buffer selection, or salt formation is not sufficient to reach the desired solubility, then the use of a cosolvent is explored. A cosolvent is a water-soluble organic solvent that is used in aqueous solution or in combination with other cosolvents to increase solubility by altering solution properties such as polarity, surface tension, and dielectric constant in poorly water-soluble drugs. Typically, if the drug molecule is slightly polar or nonpolar, then using a cosolvent to decrease the polarity of an aqueous solution will often increase the solubility (Vemuri 2010). The most common cosolvents used in injectable formulations are PG and ethanol. The combination of these two solvents is frequently used in injectable products to further modify solubility parameters. Other cosolvents (Table 6.6) that are present in marketed injectable products are polyethylene glycol 300, dimethylacetamide (DMA), and dimethylsulfoxide (DMSO).

Because the cosolvent changes many properties of the solution, the stability of the compound will also be altered. The stability of drugs susceptible to hydrolytic degradation or the formation of polar byproducts is usually improved with an increase in cosolvent concentration. The concentration of cosolvent should be selected based on solubility and stability, but it is good to remain cognizant of blood compatibility and the acceptable concentration of each cosolvent for the intended method of injection. A detailed review of cosolvent use in injectable formulations and a summary of acceptable levels for IV, IM, and SC has been provided by Strickley (2004). Some

Table 6.6 Cosolvent formulations of injectable drugs

| Molecule/indication | Composition/pH | Administration |
|---|---|---|
| Diazepam/anxiety disorders | Diazepam 5 mg, PG 40%, ethyl alcohol 10%, Sodium benzoate and benzoic acid 5%, benzyl alcohol 1.5%/pH 6.2–6.9 | Direct IV infusion with a rate not to exceed 5 mg/min |
| Dihydroergotamine mesylate/migraines | Dihydroergotamine mesylate 1 mg, alcohol 6%, glycerin 15%, sodium hydroxide to adjust pH, wfi q.s. to 1 mL/pH 3.4–4.9 | 1 mL dose by direct IV, SC, or IM injection |
| Lorazepam/epilepsy or sedative | Lorazepam 2 or 4 mg, 18% PEG400, 2% benzyl alcohol | Deep IM injection; IV injection when diluted with 1:1 volume of diluents with rate not to exceed 2 mg/min |
| Methocarbamol/sedative and musculoskeletal relaxant | Methocarbamol 100 mg, PEG300 50%, wfi q.s. to 1 mL/pH 3.5–6.0 | Direct IV injection with a rate not to exceed 3 mL/min; IV infusion diluted with no more than 250 mL of saline or D5W; IM injection |
| Phenytoin sodium/epilepsy | Phenytoin sodium 50 mg, 40% PG, 10% alcohol, sodium hydroxide to adjust pH, water for injection q.s. to 1 mL/pH 10–12.3 | Direct IV injection at a rate not to exceed 50 mg/min followed by injection with 0.9% NaCl to reduce irritation |

medications containing cosolvents can be directly injected at a slow rate; however, many are diluted (if there is no precipitation) prior to administration to reduce possible pain or injection site discomfort. After the appropriate cosolvent concentration is selected, further increases in solubility and stability can be achieved in combination with techniques previously mentioned in the chapter including pH adjustment, proper solid/salt form, and buffer selection. Other additives or techniques mentioned in the following sections can also be explored in combination with cosolvents to provide stability improvement for extended product shelf life.

An example of a molecule with essentially no aqueous solubility that utilizes cosolvents for solubilization is Lanoxin® (digoxin) injection. Delivered by either IV or IM routes of administration, digoxin injection is indicated for the treatment of mild to moderate heart failure. Digoxin is solubilized to 0.25 mg/mL in a 40%-PG, 10%-alcohol vehicle that is buffered to pH 6.8–7.2 with 0.17% dibasic sodium phosphate and 0.08% anhydrous citric acid. It is preferred for the drug product to be diluted at least fourfold into sterile water for injection, 0.9% sodium chloride injection, or 5% dextrose injection and slowly infused; however, it may be injected as IV bolus or IM, if necessary (Lanoxin Injection product monograph 2011).

6.5.4 Surfactants

When additional solubilization capacity or increased stability is required, organic amphiphilic compounds, or surfactants, are considered. Surfactants increase the

Table 6.7 Surfactant containing formulations of injectable drugs

| Molecule/indication | Composition | Administration |
|--|---|--|
| Cyclosporin A/ transplant rejection and severe rheumatoid arthritis | Cyclosporin 50 mg, Cremophor EL 65%, alcohol 32.9%, under nitrogen headspace | IV infusion over 2–6 hrs after dilution in 20–100 mL of D5W or saline |
| Doxercalciferol/ secondary hyperparathyroidism | Doxercalciferol 2 or 4 µg, ethanol 5%, Polysorbate 20 10 mg, sodium chloride 1.5 mg, butylated hydroxytoluene 0.02 mg, sodium phosphate dibasic 14.4 mg, sodium phosphate monobasic monohydrate 1.8 mg, disodium edentate 1.1 mg, wfi q.s. to 1 mL | IV bolus injection |
| Docetaxel/oncology | Docetaxel 20 mg or 80 mg concentrate in Polysorbate 80; special diluent of ethanol 13% in wfi | IV infusion over 1 hr after preparation of premix and dilution in D5w or saline for infusion admixture |
| Paclitaxel/oncology | Each mL contains Paclitaxel 6 mg, Cremophor EL 527 mg, dehydrated alcohol 49.7%, citric acid anhydrous 2 mg | IV infusion over 3 hrs after dilution to 0.3–1.2 mg/mL in D5W, saline, or dextrose 5% in lactated Ringer's injection |
| Tacrolimus/transplant rejection | Each mL contains Tacrolimus 5 mg, Cremophor RH60 200 mg, 80% dehydrated alcohol | IV infusion diluted to 4–20 µg in D5W or saline |

solubility of a compound in solution by reducing the interfacial tension between the solid particle and liquid. They are multi-component systems containing both water soluble and insoluble groups classified by the net charge of the hydrophilic head (nonionic, anionic, cationic, or amphoteric) or the chain composition of the hydrophobic tails (alkyl ether or hydrocarbon). Good candidates for surfactant-based liquid formulations typically are lipophilic, nonpolar, and nonionizable compounds which tend to be poorly water soluble.

Nonionic surfactants are widely used in the pharmaceutical industry because of relatively low toxicity and the ability to increase aqueous solubility and stability of many molecules. Commonly used nonionic surfactants in injectable products are shown in Table 6.7. When the concentration of the surfactant in an aqueous solution reaches the critical micelle concentration (CMC), they form micellar structures consisting of a hydrophobic core surrounded by an outer hydrophilic layer. These micelles have the ability to sequester lipophilic drugs within the core, thereby increasing the solubility of these molecules in aqueous formulations and protecting the drug from certain types of chemical degradation including hydrolysis, oxidation, or other methods of denaturation (Croy and Kwon 2006). However, if a multidose formulation is required, micelles can also inhibit the effectiveness of some types of preservatives by the same mechanism, which reduces the amount of free preservative in the aqueous phase.

The CMC can be changed by factors that can impact the ratio of ionic and non-ionic particles in solution, such as temperature, pH, electrolytes, or the inclusion of other surfactants or solvents (Kamat and DeLuca 2010). Therefore, characterizing the CMC value for a particular formulation is important to understand solution physical stability. It may also be beneficial to lower the CMC for more efficient solubilization with the same concentration of surfactant. Plotting the surfactant concentration versus the surface tension or using dynamic light-scattering techniques are the most common methods for determining the CMC.

Taxol® (paclitaxel) injection utilizes a combination of a cosolvent (49.7% v/v dehydrated alcohol) and a nonionic surfactant (527 mg/mL Cremophor® EL) to solubilize 6 mg/mL of the drug, which has practically no aqueous solubility. The formulation is diluted into one of the common infusion solutions and delivered IV. As is the case with many surfactant-containing formulations, it is recommended that the Taxol® infusion solution is delivered using polyolefin-coated bags and lines as opposed to plasticized PVC due to the potential for leaching the plasticizer into the formulation (Taxol 2010).

6.5.5 Cyclodextrins

A poorly water-soluble compound may be a good candidate for solubility by complexation, an interaction that forms water-soluble dynamic (reversible) covalent inclusion complexes with cyclodextrins. Cyclodextrins are cyclic oligosaccharides six to eight dextrose units in length connected by 1, 4 bonds that have a hydrophilic exterior with a more lipophilic core. The solubilizing capacity of a cyclodextrin depends on a number of factors including the structure of the drug molecule, size of the inclusion cavity, stoichiometry of the complex, the complexation equilibrium constant, and the overall free energy of the system (Challa et al. 2005). Most types of cyclodextrins are slightly soluble in water, which limits use in aqueous solutions that typically require a relatively high concentration of cyclodextrin for solubilization. The low water solubility of most cyclodextrins also poses a toxicity issue for IV products because of potential precipitation post administration, specifically in the kidney (Shi et al. 2009).

For injectable drugs, the most common complexation agents are two modified forms of cyclodextrins, hydroxypropyl- β -cyclodextrin (HP- β -CD) and sulfobutylether- β -cyclodextrin (SBE- β -CD). These two forms of cyclodextrin demonstrate efficient complexation capability, high water solubility (>500 mg/mL), increased solubilizing capacity, and reduced in vivo toxicity (Challa et al. 2005). Complexes are typically formed as 1:1 interactions, although other inclusions of higher order can occur where complexed molecules are in rapid dynamic equilibrium with the free molecules in solution. Therefore, it is critical to determine how the amount of free drug in solution and within inclusion complexes changes as a function of cyclodextrin concentration. This relationship can be determined by using a number of techniques discussed in the literature (Thompson 1997; Loftsson et al. 2005). Also, when a compound forms a complex, it can alter the physiochemical and biological properties of the drug, which may or may not result in enhanced solubility and stability (Table 6.8).

Table 6.8 Cyclodextrin containing formulations of injectable drugs

| Molecule/indication | Composition/pH | Administration |
|---|--|--|
| Intraconazole/ antifungal | Each mL contains Intraconazole 10 mg, HP- β -CD 400 mg, hydrochloric acid 3.8 μ L, PG 25 μ L, sodium hydroxide for pH adjustment, wfi to q.s./pH 4.5 | IV infusion after dilution in 50 mL of saline |
| Voriconazole/ antifungal | Lyophilized powder in 30 mL vial containing Voriconazole 200 mg, SBE- β -CD 3,200 mg | IV infusion over 1–2 hrs following reconstitution to 10 mg/mL with wfi and further dilution with saline, D5W, or lactated Ringer's injection |
| Ziprasidone mesylate/ antipsychotic | Lyophilized powder with each mL containing ziprasidone 20 mg, methanesulfonic acid 4.7 mg, SBE- β -CD 294 mg upon reconstitution with 1.2 mL wfi | IM injection of 0.5 or 1.0 mL to deliver a 10 or 20 mg dose |

Geodon[®] (ziprasidone mesylate) for injection is an atypical antipsychotic presented as a single-dose IM product. The drug product is a lyophilized form of ziprasidone mesylate trihydrate and contains 20 mg/mL ziprasidone, 4.7 mg/mL methanesulfonic acid, and 294 mg/mL SBECd once reconstituted.

6.5.6 *Nonaqueous/Oily Vehicles*

If sustained IM delivery is acceptable, the most straightforward approach to solubilize lipophilic drugs is to utilize a nonaqueous, oily solution as the formulation vehicle. There are many examples of long-acting IM injections of drugs in oil vehicles, one of which is Haldol[®] (haloperidol decanoate) Injection. This formulation is available in 50 or 100 mg/mL drug concentrations in sesame oil vehicles with benzyl alcohol as a preservative. Haldol[®] is used for prolonged antipsychotic therapy as a once monthly depot injection (Haldol 2011).

6.6 Other Solubilization Techniques

6.6.1 *Emulsions*

Emulsions, which are heterogeneous dispersions of two immiscible liquids, are used regularly in the food industry and have some applications in the pharmaceutical industry as well. Emulsions are produced by adding mechanical energy to a water and oil system, resulting in droplets that can be stabilized using an emulsifying agent. Depending on which phase is continuous and which is dispersed, the emulsion can be referred to as an oil-in-water (o/w) or water-in-oil (w/o) emulsion. Emulsions are thermodynamically unstable and are prone to flocculation, creaming, and coalescence

if not adequately stabilized and stored under a controlled (usually refrigerated) temperature for the duration of the product shelf life. The most common injectable application of emulsions are o/w products administered intravenously for the purpose of patient nutrition, of which the earliest approved for human use was Intralipid®. These IV nutrient emulsions are comprised of soybean and/or safflower oil, egg phospholipids, and glycerin in water for injection and have a droplet diameter of 400–500 nm. Due to the complexity of emulsion formulations, there have been very few marketed commercial products which utilize this approach for drug solubilization and delivery. Many that have been investigated have either been prepared with or had similar compositions to the described nutrient emulsions and were mostly delivered intravenously.

The anxiolytic-sedative compound diazepam is formulated as Diazemuls® (diazepam injectable emulsion) due to its low aqueous solubility. It is administered either IV or IM and at doses of 2–20 mg, depending on the indication. Each milliliter of diazepam emulsion contains 5 mg of diazepam dissolved in the oil phase (150 mg purified soybean oil and 50 mg acetylated monoglycerides) of an o/w emulsion also containing 12 mg purified egg phospholipids, 22 mg anhydrous glycerol, and sodium hydroxide for adjustment to pH 8. It is desired to administer the formulation as is, but it is acceptable to perform necessary dilutions with Intralipid®. The formulation has a mean lipid particle diameter of 180 nm, and the drug has to be released from the oil phase in order to have a therapeutic effect (Diazemuls 1998).

Additionally, research has been executed on the applicability of more complex emulsion-based formulation approaches such as multiple emulsions, microemulsions and self-emulsifying drug delivery systems (SEDDS), which are beyond the scope of this chapter (Singh et al. 2009).

6.6.2 Liposomes

Liposomes are drug carriers appropriate for the delivery of lipophilic or hydrophilic drugs. These vesicles are assembled as an aqueous core enclosed by amphiphilic lipids, which are usually bilayer-forming phospholipids. Depending on the number of lamellae and size, liposomes are categorized as small unilamellar vesicles (SUVs), large unilamellar vesicles (LUVs), large multilamellar vesicles (MLVs), or multivesicular vesicles (MVVs). A benefit to this solubilization approach is that the encapsulated drug can reach its targeted site more effectively than traditional dosage forms due to the unique distribution and elimination of liposomes in the body (Kamat and DeLuca 2010). Additional information on the composition, characterization, and production of liposomes can be found in “Liposomes – A Practical Approach” (Torchilin and Weissig 2003).

DaunoXome® (daunorubicin citrate liposome injection) was developed to maximize the selectivity of the molecule for solid tumors. Encapsulation of the daunorubicin within a lipid bilayer significantly decreases the plasma clearance and volume of distribution in comparison to the conventional HCl salt lyophilic formulation delivered in an aqueous-based vehicle. Though the specific mechanism is not known, animal studies have shown daunorubicin to accumulate in tumors to a greater extent when

administered as the liposomal formulation relative to the conventional IV drug product (DaunoXome 1996). It is hypothesized that the 45 nm average mean diameter allows the liposomes to improve the permeability of the molecule into the tumor neovasculature. DaunoXome® contains daunorubicin citrate equivalent to 50 mg of daunorubicin base encapsulated in liposomes consisting of 704 mg distearoylphosphatidylcholine (DSPC) and 158 mg cholesterol. These liposomes are dispersed in an aqueous medium containing 2,125 mg sucrose, 94 mg glycine, and 7 mg calcium chloride dehydrate in a total volume of 25 mL/vial. The pH is between 4.9 and 6.0, and the dispersion should appear red and translucent. Daunorubicin citrate liposome is stored at 2–8°C prior to use and is instructed to be diluted 1:1 with D5W and delivered intravenously over 60 min.

6.6.3 Suspensions

In cases where the desired drug load exceeds the solubility limitations using any number of solubilization techniques or when a controlled release formulation is desired, the approach of developing a suspension formulation may be appropriate. Most suspensions are intended principally for IM and SC injection and tend to be more complex to develop than solution dosage forms. Sterilization, particle size distribution, physical stability (Ostwald ripening, caking, resuspendibility, etc.), syringeability, dose homogeneity, and injection site toleration are some of the many complications that arise when developing suspension formulations. Processing involves either aseptically combining sterile vehicle and powder prior to filling or combining sterile solutions of the drug and vehicle to form the suspension in situ. Classic suspensions in which a poorly soluble API is suspended in either an aqueous or oily vehicle are routinely developed; however, other types of dispersion approaches, such as microspheres, have also been developed to deliver high doses of various drugs over an extended period of time (Sinha and Trehan 2005).

An example of an injectable microsphere formulation is Vivitrol® (naltrexone for extended-release injectable suspension), which is an opioid antagonist. Microspheres are polymeric spherical particles often used to achieve a sustained drug concentration. The anhydrous base utilized in the Vivitrol® formulation is practically insoluble in water, and the formulation is administered once a month as an IM depot injection. The drug product is comprised of 337 mg naltrexone per g of 75:25 polylactide-co-glycolide (PLG) microspheres provided as a dry powder in a vial. A sterile diluent consisting of carboxymethylcellulose sodium salt (NaCMC), polysorbate 20, sodium chloride, and water for injection is provided and used to suspend the microspheres at the time of dosing. A volume of 3.4 mL of diluent is added to the microsphere vial to attain an ~90 mg naltrexone per mL suspension for injection. (Vivitrol 2010)

6.6.4 Nanosuspensions

To achieve high drug loading for compounds with either poor solubility in water, lipids, and/or organic solvents, nanosuspensions can be considered. Additionally, by

formulating an injectable as a nanosuspension, drug loading per unit volume can be substantially increased, reducing the overall volume of injection. Nanosuspensions are colloidal dispersions of sub-micronized drug particles, which can be produced by both top-down and bottom-up preparation methods. The use of mechanical energy to reduce particle size (top-down) can be accomplished through a variety of grinding, milling, and homogenization techniques and is described in detail in another chapter of this book. For preparation of an injectable nanosuspension, high-pressure homogenization has been proven effective (Mishra et al. 2010). Other bottom-up approaches usually represent a more controlled approach to particle production, where nucleated particles are “built” upon in an environment where solubility is limited. These techniques may involve antisolvent-, temperature-, salt-, or supercritical fluid-induced precipitation and are often stabilized by surface-active agents. Controlled precipitation approaches are also described in more detail in another chapter.

For a drug with poor water solubility, there are several advantages to formulating as a nanosuspension. Most obviously, since the drug is not required to be in solution, drug loading can be increased so that the volume of injection is greatly reduced. Additionally, potentially toxic agents used to increase drug solubility (e.g., Cremophor) can be avoided and replaced with low levels of more tolerable agents (e.g., phospholipids). One other advantage, often found in nanosuspensions of cancer therapeutics, is that the nanoparticles can alter the pharmacokinetics and targeting capability of a specific drug substance. Many researchers have added “stealth” properties to nanoparticles by encapsulating them in liposomes or coating the surface with polyethylene-glycol-conjugated polymers (Gabizon 2001). By increasing the duration of systemic circulation and avoiding clearance into the RES, these formulations have been found to target malignancies through the enhanced permeation and retention effect (Mishra et al. 2010). Many of the issues experienced with suspensions, such as foreign matter contamination and sterilization, also apply to nanosuspension formulations. Due to the particle size reduction, a syringeability benefit can be obtained and high doses of drug can potentially be loaded into a nanosuspension formulation. In addition to IM and SC routes of administration, a nanosuspension has recently been approved for IV administration (Wong et al 2008).

The first nanosuspension approved for intravenous use was Abraxane[®] (albumin-bound paclitaxel), a reformulation of the chemotherapeutic Taxol[®]. In this formulation, high-pressure homogenization of human serum albumin and paclitaxel followed by controlled removal of solvents resulted in formation of albumin-associated drug nanoparticles with a mean diameter of 130 nm. The stabilized drug nanoparticles are redispersed to form a small-volume colloidal dispersion for a 30 min intravenous infusion. Taxol[®], commonly used in the treatment of lung, breast, and ovarian cancer, is often associated with hypersensitivity and nonlinear pharmacokinetics due to the inclusion of the solubility-enhancing agent, polyoxyethylated castor oil (Cremophor EL). To offset the immunological response induced by Cremophor, a course of Taxol[®] is preceded by antihistamine and corticosteroid administration. Additionally, infusions of Taxol[®] require approximately 3 h due to the large volume need to solubilize the entire dose of paclitaxel. Reformulation of paclitaxel into an albumin-bound nanoparticle has provided several advantages over the preexisting therapy, most of which

result from the elimination of Cremaphor EL. Avoidance of Cremaphor eliminates the need for anti-inflammatory premedication and simplifies the drug pharmacokinetic profile from pseudo-nonlinear to linear (van Tellingen et al. 1999). It is believed that Cremaphor micelles entrap paclitaxel in circulation and control the amount of “free” circulating paclitaxel available for distribution and elimination. Other complications caused by the inclusion of Cremaphor include the need for nonleachable infusion equipment and longer infusion time. Furthermore, preclinical studies have shown that Abraxane[®] is more efficacious than traditional paclitaxel therapy, likely due to the heightened intratumoral concentrations afforded by albumin transport (Desai et al. 2006). The reformulation of the paclitaxel as a colloidal dispersion for infusion demonstrates the multiple advantages that can be afforded by taking a more advanced formulation approach to address poor solubility, while improving overall tolerability.

Invega[®] Sustenna[®] (paliperidone palmitate prolonged release injectable suspension) is an example of an extended release IM depot formulation utilizing nanoparticles to achieve high doses (100 mgA/mL equivalent to 156 mg/mL paliperidone palmitate). It is supplied as various volumes loaded into prefilled syringes to provide four doses ranging from 50 to 150 mg of paliperidone for use as a once-monthly treatment for schizophrenia. The formulation contains citric acid monohydrate, disodium hydrogen phosphate anhydrous, PEG 4000, polysorbate 20, sodium dihydrogen phosphate monohydrate, and sodium hydroxide and water for injection. Particle size reduction is achieved using Elan’s NanoCrystal[®] technology, which is an attrition-based milling technique (Invega[®] Sustenna[®] 2011).

6.7 Strategies for Improving Stability

Once the drug is solubilized to the required concentration by any of the aforementioned techniques, the physicochemical stability of the formulation must be assessed. The shelf life and storage conditions of the formulation will be limited by the degradation of the molecule. If needed, when stability is not adequate, any of a number of techniques can be used to improve it. Two broad categories of stability improvement strategies are additives and processing techniques. The following sections will discuss how to use these techniques to improve the stability of compounds prone to hydrolysis and oxidation, two of the major chemical degradation pathways for small-molecule drugs (Vemuri 2010).

6.7.1 Additives

Although buffer systems assist in controlling the pH of a vehicle, the level and type of buffer must be carefully selected as to not negatively impact the solubility and stability of the drug. It is important in early screening studies to assure that the selected buffer does not cause precipitation of a low-solubility salt form of the drug. Also, depending on the degradation pathways for a given drug, a buffer can negatively impact stability by acting as a general acid or general base catalyst.

Table 6.9 Commonly used antioxidants in injectable drugs

| Antioxidant | Typical concentration (%) |
|--------------------------------|---------------------------|
| Ascorbic acid | 0.01 |
| Butylated hydroxyanisole (BHA) | 0.02 |
| Butylated hydroxytoluene (BHT) | 0.02 |
| Cysteine | 0.5 |
| Monothioglycerol | 0.5 |
| Sodium bisulfite | 0.15 |
| Sodium metabisulfite | 0.2 |
| Glutathione | 0.1 |

Oxidative degradation is catalyzed by metal, hydrogen, and hydroxyl ions. The issue of oxidation can be addressed either by displacing the oxygen from the vial and/or by adding a single antioxidant or various combinations of antioxidants and chelating agents to the formulation. In addition, trace amounts of oxidation catalyzing impurities (especially heavy metals and peroxides) can be introduced into the formulation by ingoing excipients, so even a well-controlled oxygen displacement process would require high-purity excipients to limit these trace impurities. The addition of antioxidant(s) and/or chelating agent(s) to the formulation can improve the stability of oxidation-prone drugs. A list of antioxidants used in injectable products is shown in Table 6.9. A true antioxidant, such as sodium bisulfite, reacts with free radicals to terminate the oxidative chain reaction; a reducing agent (e.g., citric acid) is preferentially oxidized and reduces the level of oxygen or oxidant in the formulation; a chelating agent, such as ethylenediaminetetraacetic acid (EDTA), complexes with trace metals present in the drug product thereby blocking the oxidative degradation pathway (Kasra et al 1999). Sometimes, a synergistic approach is utilized by in order to increase the overall antioxidant effectiveness. As with any excipient, it is important to assess the regulatory acceptability of the antioxidant/chelating agent. Also, depending on the properties of the drug molecule, the antioxidant may either improve or worsen the solubility of the drug in the formulation.

6.7.2 Processes

As noted above, oxidation can be prevented or minimized by the process of removing the oxygen from the primary container closure. Sparging, bubbling a chemically inert gas through the drug solution prior to filling and sealing vials, and/or blanketing the vials with nitrogen are common processing techniques for improving the stability of injectable formulations sensitive to oxidative degradation. This method is often used as a means to reach the target product shelf life, but it can be difficult to control, and some manufacturing facilities may not have the equipment to allow for this approach.

Hydrolytic degradation is commonly addressed in hydrolysis-prone injectable products by either removing the water from the formulation until administration or by formulating the drug as a dispersion of solid particles of an essentially insoluble form to isolate the drug from the water. The seemingly simplest approach is filling

dry powder into vials, which can then be constituted. For an injectable product, the powder must be sterile and aseptically filled into vials, but minimizing foreign matter contamination and maintaining sterility can be difficult. Powder flow properties and particle size can impact the complexity of filling and constituting the drug product. To improve the robustness of the aseptic process, the product can be crystallized or spray dried from a sterile filtered solution.

A common, more robust method of improving formulation stability for hydrolysis-prone injectable molecules is using a processing approach known as lyophilization. Also referred to as freeze drying, lyophilization is a process by which water present in the formulation is essentially removed for storage and restored during reconstitution immediately prior to administration. In addition to the stability benefit, lyophilization also generally provides a solubility benefit. During processing, the drug solution transitions into a porous amorphous solid cake, which is more easily wetted than crystalline forms of the same drug and has the highest thermodynamic solubility due to the absence of an ordered crystal lattice. The freeze-drying process parameters can be manipulated to improve the porosity and therefore the reconstitution time of the cake.

A solution of the drug, other required formulation components, and sometimes a bulking agent (an excipient used to create the structure and integrity of the dried cake) is aseptically filled into vials and loaded into a freeze-drying unit with shelves that can be temperature controlled. The freeze-dryer controller is programmed with a lyophilization process, which includes the steps of freezing, evacuation, primary drying, and secondary drying. Though the process tends to be long and costly, it has been extensively studied, well characterized, and routinely used.

In addition to the intrinsically low-solubility compounds mentioned in the previous section, compounds susceptible to hydrolysis in solution can be good candidates for suspension formulations. By selecting a low-solubility form of the API, one is able to essentially isolate the drug from the surrounding vehicle, therein improving stability. This type of suspension can be designed as either ready to use or a powder fill to be constituted at the time of use with a sterile diluent. Another approach to consider, especially if aqueous solubility is too high, is using a nonaqueous solvent, such as a vegetable oil, as the suspending vehicle. As was mentioned previously, physical stability can be challenging when developing any suspension formulation; however, chemical stability tends to be rather robust and can be monitored by dissolving the drug in a suitable solvent for assay/purity analysis during stability testing.

6.8 Injectable Product Development Work-flow

As evident from the preceding information in this chapter, the process of developing an injectable product for a poorly water-soluble compound is a dynamic multi-variable process. The specific properties of the drug and the intended route of administration will dictate the most likely path forward in the formulation development process. As more data are generated (solubility, stability, etc.), the required formulation attributes become more defined. An example flowchart demonstrating the steps in this process is displayed in Fig. 6.1.

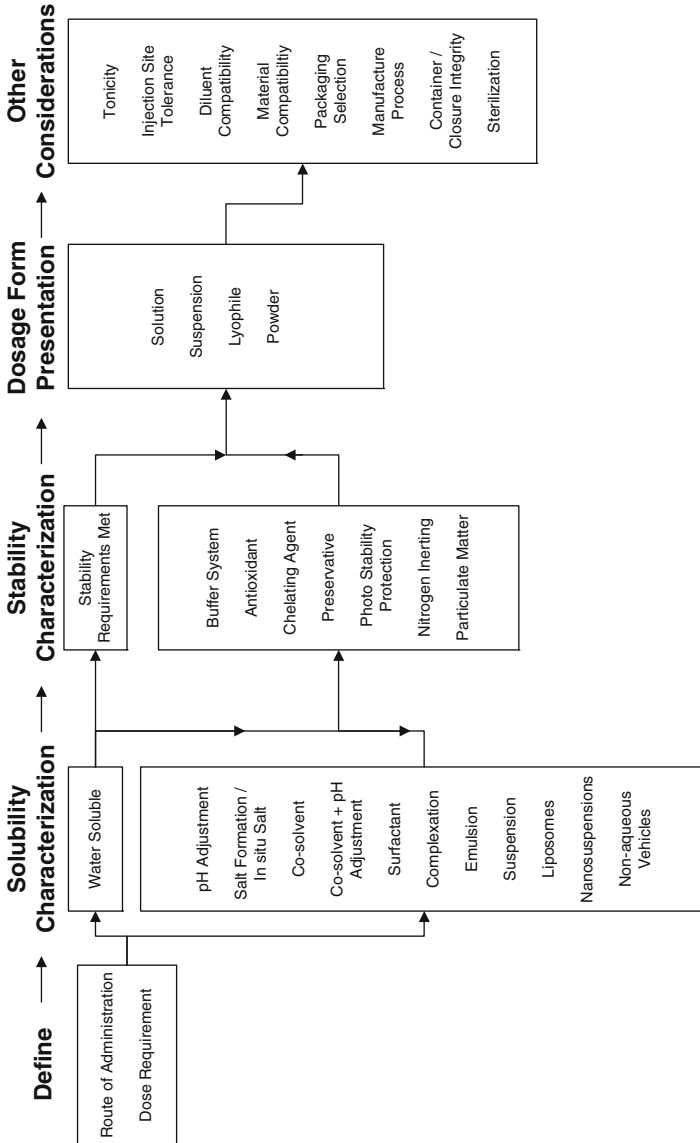

Fig. 6.1 Injectable Product Development Flowchart

Method Capsule 1

Solubilization of a Poorly Water-Soluble Drug Using a Surfactant with pH Adjustment

Based on the method reported by Li et al. (1999a).

Objective

- To increase the solubility of flavopiridol, an antineoplastic agent with a water solubility of 0.025 mg/mL, by changing the solution pH and incorporating a surfactant.

Equipment and Reagents

- Flavopiridol (apparent pK_a 5.86).
- Polysorbate 80 (PS80).
- Citrate buffer.
- End-over-end mechanical rotator operating at 20 rpm.
- Pinnacle octylamine HPLC column (150 cm x 4.6 mm).
- Mobile phase of 0.1% triethylamine in 50 mM phosphate buffer pH 2.5 and acetonitrile in a ration of 35:65 (flow rate 1 mL/min; detection 263 nm).
- Syringe filter unit (0.45 μ m).
- pH meter.

Method

- Prepare solutions of varying concentrations of PS80 (0, 2.5, 5, 10, and 20%) in citrate buffer with a pH of 4.3 and 8.4.
- Perform solubility study by placing 0.5 mL of each solution into vials with excess flavopiridol.
- Attach vials to rotator, place at 25°C, and rotate at 20 rpm for 6 days or until equilibrium solubility is achieved. (Note: The drug is stable for >2 months under these conditions).
- Filter samples through 0.45- μ m syringe filter membrane and check final solution pH.
- Perform HPLC analysis of samples for potency (solubility) of flavopiridol.

Results

- The solubility of flavopiridol in solution without surfactant was 1.37 mM and 0.055 mM at pH 4.3 and 8.4, respectively.
- The solubility of a drug in the micelle is influenced by the micellar partition coefficient and drug water solubility.
- Increasing the concentration of PS80 resulted in a substantial linear increase in drug solubility. The increase was considerably greater (up to ~27 mM at 20% PS80) at pH 4.3, where the majority of drug is ionized.
- Solubilization of the ionized drug by PS80 is more critical than that of the unionized species for increasing the overall solubility due to the increased water solubility resulting from the increased solubility of drug in the micelles.

Method Capsule 2

Solubilization of a PWS Drug using a Combination of Cosolvent and Surfactant

Based on the method reported by Dong et al. (2008).

Objective

- To develop a stable injectable solution of N-epoxymethyl-1,8-naphthalimide, a nonionizable PWS drug (0.0116 mg/mL) that is very susceptible to hydrolytic degradation by screening a number of solubilization techniques.

Equipment and Reagents

- N-epoxymethyl-1,8-naphthalimide (ENA).
- Cosolvents: ethanol, polyethylene glycol 400 (PEG-400), PG, and glycerol.
- Surfactants: Cremophor EL and Tween 80.
- Complexation agents: HP β CD and hydroxypropyl- γ -cyclodextrin (HP γ CD).

Method

- Determine the solubility of ENA in cosolvent–water solutions with concentrations up to 50% (w/v).
- Determine the solubility of ENA in surfactant–water solutions with concentrations up to 20% (w/v).
- Determine the solubility of ENA in aqueous solutions containing up to 20% (w/v) cyclodextrins.
- Based on the results from the above solubility studies, determine the solubility of ENA in nonaqueous solution containing different ratios of the best performing solubilizers: Cremophor EL and ethanol (0:100, 50:50, 60:40, 70:30, and 100:0% v/v).
- Select a number of ratios of Cremophor EL:ethanol from the previous stability study and assess formulation stability upon dilution with saline.
- Assess formulation physical and chemical stability at different storage conditions.

Results

- Aqueous solutions containing concentration of 50% ethanol, PEG400, PG, or glycerol have an ENA solubility of 0.531, 0.269, 0.181, and 0.038 mg/mL, respectively.
- The solubility of ENA is increased to 0.395 and 0.410 mg/mL with 20% of Tween 80 and Cremophor EL, respectively.
- The solubility of ENA is increased to 0.169 and 0.190 mg/mL with 20% of HP β CD and HP γ CD, respectively.
- Cremophor EL:ethanol ratios of 0:100, 50:50, 60:40, 70:30, and 100:0 increased the solubility of ENA to 1.25, 3.90, 4.54, 5.42, and 6.65, respectively.
- Of all the ratios screened, only a combination of 70% Cremophor EL and 30% ethanol containing 4 mg/mL of ENA did not precipitate upon dilution (5- to 20-fold) with saline. This formulation is physically and chemically stable for over 4 months at either 5°C or room temperature.

Method Capsule 3

Solubilization Using a Combination of Complexation Agent and Cosolvent

Based on the method reported by Li et al. (1999b).

Objective

- To increase the solubility of fluasterone, a nonpolar oncology compound, using various amounts of cosolvent (ethanol) in combination with the complexation agent hydroxyl propyl- β -cyclodextrin (HP β CD).

Equipment and Reagents

- Fluasterone (intrinsic solubility 0.045 $\mu\text{g}/\text{mL}$)
- Ethanol
- HP β CD
- End-over-end mechanical rotator operating at 20 rpm
- Pinnacle octylamine HPLC column (150 cm x 4.6 mm)
- Mobile phase of 75% acetonitrile in water (flow rate 1.1 mL/min; detection 220 nm)
- Syringe filter unit (0.45 μm)
- pH meter

Method

- Prepare solutions of varying concentrations of ethanol (0–70%) and HP β CD (0–20%).
- Place 0.5 mL of each solution into glass vials with excess flavopiridol.
- Connect vials to rotator, place at 25°C, and rotate at 20 rpm for 6 days or until equilibrium solubility is achieved. (Note: The drug is stable for >50 days under these conditions).
- Filter samples through a 0.45- μm syringe filter membrane and check final solution pH.
- Perform HPLC analysis of samples for potency of fluasterone.

Results

- An exponential increase in the solubility of fluasterone is observed in a cosolvent and water system with increasing ethanol concentration.
- Using HP β CD in an aqueous solution yields a linear increase in drug solubility corresponding with increasing HP β CD concentration.
- As ethanol concentration increases from 0.2 to 25.06% in the presence of HP β CD, the polarity of the solvent decreases. The result is reduced drug complexation within the HP β CD cavity and a decrease in the drug solubility over this range, with a minimum at 25.06%.
- At high ethanol concentrations (25.06–75%), the solubility increases due to the increase in the concentration of free drug and ternary complex.
- With the ethanol concentration held constant (>25.06%), there is a linear increase in drug solubility with increasing amounts of HP β CD.

Method Capsule 4

Preparation of a Submicronized Injectable Emulsion Formulation

Based on the method reported by Levy and Benita (1989).

Objective

- To design and characterize an emulsion formulation for diazepam, which meets the requirements for an IV or IM administration.

Equipment and Reagents

- Diazepam
- Purified soybean oil
- Egg yolk phospholipids (purified fractionated complex emulsifier)
- Poloxamer (nonionic emulsifier)
- Glycerin (osmotic agent)
- Methyl and butyl p-hydroxybenzoic acid (preservative)
- α -Tocopherol (antioxidant)
- Sodium hydroxide solution (10%)
- High-shear mixer (Polytron)
- Two-stage pressure homogenizer (Gaulin homogenizer)

Method

- The formulation is composed of 0.5% (w/w) diazepam, 20% oil, 1.2% phospholipids, 2% poloxamer, 2.25% glycerin, 0.02% α -tocopherol, 0.2% methyl and 0.075% butyl p-hydroxybenzoic acid, and water for injection to 100 g.
- Perform preparation and processing with nitrogen atmosphere and sterile conditions.
- Add poloxamer, glycerin, and preservatives to the aqueous phase and dissolve.
- Dissolve phospholipids and diazepam in the oil phase containing α -tocopherol.
- Filter both phases, and heat separately to 70°C while mixing with a magnetic stirrer. Increase the temperature to 85°C for the emulsification step using the high-shear mixer.
- Once the emulsion is formed, cool rapidly. A reduced droplet size is achieved using the two-stage Gaulin homogenizer. Adjust pH to the desired level with sodium hydroxide and filter the emulsion.

Results

- Characterization of the formulation including the oil phase properties, pH, phase/volume ratio, emulsifier, phospholipid, nonionic emulsifier, and diazepam concentrations produced an optimized stable emulsion.
- Droplet size was reduced to an acceptable size for IV administration from a mean size of 0.65 μm by a high-shear mixer to 0.27 μm , using the Gaulin two-stage pressure homogenizer.

Method Capsule 5

Preparation of Multivesicular Liposome Formulation for Sustained IM Delivery

Based on the method reported by Zhong et al. (2005).

Objective

- To design a multivesicular liposome (MVL) sustained delivery formulation for IM injection.

Equipment and Reagents

- Breviscapine (bioactive ingredient)
- Phosphatidylcholine
- Phosphatidylglycerol
- Triolein or tricaprylin
- Cholesterol
- Sucrose and glucose
- Buffers: 50 mM arginine buffer pH 7, 40 mM L-Lysine
- Chloroform–diethyl ether (1:1 v/v)
- T 18 basic Ultra-Turrax mixer

Method

- Use the double-emulsion process to produce breviscapine MVLs. Prepare a lipid mixture in 1 mL chloroform–diethyl ether with 40 mg phosphatidylcholine, 8 mg phosphatidylglycerol, 40 mg cholesterol, and triolein or tricaprylin at a 5.75:1 molar ratio of phosphatidylcholine to total triglyceride content.
- Prepare an aqueous solution containing 40 mg/mL of breviscapine, 4% w/v sucrose in 50 mM arginine buffer pH 7.
- Emulsify the lipid and aqueous solutions to make a W/O emulsion at 10,000 rpm for 8 min with the mixer.
- Prepare the second aqueous solution with 40 mM L-Lysine and 3.4% glucose and emulsify with the W/O emulsion to form a W/O/W emulsion. Transfer to an Erlenmeyer flask and remove the chloroform–diethyl ether by nitrogen flushing the liquid surface at 30°C.
- Centrifuge at 600g for 5 min to remove free breviscapine from the MVLs and resuspend in a buffered saline solution.

Results

- Breviscapine MVLs produced by this method significantly prolonged the release of drug both in vitro (5–6 days) and in vivo (IM injection in rats lasted 4–5 days) compared to other the liposome preparation techniques investigated.

Method Capsule 6

Preparation of Nanoemulsions for IV Delivery

Based on the method reported by Kelmann et al. (2007).

Objective

- To prepare a nanoemulsion for IV delivery of a PWS drug, carbamazepine.

Equipment and Reagents

- Carbamazepine (CBZ)
- Ethanol
- Acetone
- Soybean lecithin (lipophilic emulsifier)
- Medium chain triglycerides (MCT)
- Polyoxyl 35 castor oil (lipophilic emulsifier)
- Polysorbate 80 (hydrophilic emulsifier)
- Glycerol (tonicity agent)
- Magnetic stirrer

Method

- Mix CBZ (final emulsion concentration of 2 mg/mL) with castor oil or a 1:1 mixture of castor oil:MCT (w/w) and prepare the lipophilic emulsifier (soybean lecithin or polyoxyl 35 castor oil at 6% w/w) by dissolving it in a 50:50 mixture of acetone:ethanol (v/v).
- Make the oil phase by adding the prepared emulsifier to the drug:oil dispersion.
- Prepare the aqueous phase by dissolving 4% (w/w) PS80 and 2.5% (w/v) glycerol in water.
- While stirring (moderate speed) with a magnetic stirrer, slowly add the oil phase to the aqueous phase to form the nanoemulsion.
- Remove solvent and water by reducing the pressure, adjust pH to 7.0 with 0.1 M sodium hydroxide, and store the emulsion at 5°C.

Results

- The emulsion droplets are spherically shaped, have an amorphous core, and range in size from 100 to 250 nm.
- The resulting optimized nanoemulsion formulation demonstrates 3 months stability based on droplet size, polydispersity, zeta potential, and drug content data.
- The drug nanoemulsion meets requirements for IV administration and will be tested for in vivo evaluation.

Method Capsule 7

Preparation of an IV Nanosuspension Formulation for Reduced Irritation and Phlebitis upon Injection

Based on the method reported by Xiong et al. (2007).

Objective

- To improve upon a current clinical IV formulation for nimodipine, which contains a high concentration of ethanol that causes injection site pain, irritation, and phlebitis.

Equipment and Reagents

- Nimodipine (compound for the treatment of subarachnoid hemorrhage-related vasospasm)
- Sodium deoxycholate
- Poloxamer 188
- Mannitol
- Polysorbate 80
- MC One (fluid jet mill)
- Niro-Soavi NS1001L (high-pressure homogenizer)
- Laboratory freeze drier

Method

- Perform all the following steps under reduced lighting conditions to protect the light-sensitive drug.
- Jet mill the coarse powder of nimodipine to produce a microparticulate powder.
- Disperse with a magnetic stirrer 0.5% (w/v) the milled powder in an aqueous solution composed of 0.6% (w/v) poloxamer 188, 0.4% (w/v) sodium cholic acid, and 4.0% (w/v) mannitol.
- Perform pre-milling using the high-pressure homogenizer (maintain sample temperature at 25–30°C) by starting with the settings at 200 bar with two cycles then increasing to 500 bar with five cycles.
- Follow the pre-milling step with 15–20 cycles at 1,500 bar to produce the nanosuspension.
- Lyophilize the nanosuspension by drying for 15 hr at –15°C (below 200 mTorr), with a secondary step of 3 hr at –5°C, and a final step of 2 hr at 20°C.
- Sterilize by gamma irradiation for 6 hr with an absorbed dose of 12 kGy.

Results

- Injection toleration studies performed in rabbits demonstrate that this formulation reduces occurrence of phlebitis and minimizes local irritation when compared with the clinical ethanol-based product.

Chapter 7

Design and Development of Self-Emulsifying Lipid Formulations for Improving Oral Bioavailability of Poorly Water-Soluble and Lipophilic Drugs

Ping Gao

Abstract This chapter discusses possible in vivo absorption pathways associated with lipid-based formulations. An understanding of such pathways could enable scientists to manipulate formulation approaches intended to improve the rate and extent of absorption of poorly water-soluble, lipophilic drugs. The chapter focuses on several in vitro test methods specifically applicable to lipid-based formulations. These tests play an important role in characterizing key formulation attributes that may be responsible for bioavailability improvement. The relevance of these in vitro test results with respect to the in vivo bioavailability data is addressed through individual case studies as examples. Appropriate in vitro characterization results are critical in providing a scientific understanding of solubilization and supersaturation phenomena and their effect upon pharmacokinetic profiles of poorly soluble drugs in preclinical species and in human subjects.

7.1 Introduction

The oral administration of highly lipophilic, poorly water-soluble drugs often results in poor and highly variable bioavailability due to poor dissolution in vivo. One approach for improving the absorption of these drugs involves the use of self-emulsifying formulations or SEDDS that gained popularity in the past two decades (Müllertz and Ogbonna 2010; Fricker et al. 2010; He et al. 2010; Cannon and Long 2008; O’Driscoll and Griffin 2008; Pouton and Porter 2008; Porter and Pouton 2008; Trevaskis et al. 2008; Chen 2008; Porter et al. 2007; Strickley 2007; Gao and Morozowich 2007a, b). The SEDDS formulations usually rapidly disperse following

200 Abbott Park Road, Abbott Park, IL 60064, USA
e-mail: ping.gao@Abbott.com

oral administration and yield an o/w emulsion or microemulsion containing the solubilized drug.

SEDDS formulations are typically developed by an empirical, trial-and-error approach, although some useful guidelines have emerged from characterization of successful formulations such as Neoral[®] of cyclosporine A (Strickley 2007). The literature on microemulsion formulations describes a multitude of compositions and functional characteristics producing varying degrees of drug absorption enhancement in both animals and humans (Müllertz and Ogbonna 2010; Fricker et al. 2010; He et al. 2010; Cannon and Long 2008; O'Driscoll and Griffin 2008; Pouton and Porter 2008; Porter and Pouton 2008; Trevaskis et al. 2008; Chen 2008; Porter et al. 2007; Strickley 2007; Gao and Morozowich 2007a, b). Formulation scientists are frequently presented with a series of challenging decisions during the development of SEDDS formulations including choice of formulation strategy, excipient selection, solubility and stability assessment, formulation optimization, and scale-up and production of the final product.

The generation of a microemulsion following aqueous dilution of an SEDDS requires a high surfactant concentration relative to the other formulation components; an insufficient amount of surfactant can yield increase propensity for drug precipitation (Gao and Morozowich 2007b). Application of supersaturatable S-SEDDS formulations enables another important approach to improve the rate and extent of absorption of poorly soluble drugs via yielding and sustaining a supersaturated state in vivo. In general, the selection of the lipid for the SEDDS formulation is commonly based on the physical and/or interfacial characteristics of the resulting formulation with limited understanding of the influence of lipid upon drug solubilization and absorption. The selection of a lipid for optimal enhancement of in vivo absorption of the drug is often an iterative, empirical, and labor-intensive process.

This chapter describes the design and development of SEDDS and S-SEDDS formulations of highly lipophilic and poorly soluble drugs with emphasis on in vitro characterizations of key formulation attributes and their relevance to in vivo performance. Influence of the SEDDS formulation variables reflected by the in vitro performance and exposure observed in animals and in humans is presented along with case examples. We hope this review describes a systematic approach for developing SEDDS and supersaturatable S-SEDDS formulations of poorly water-soluble, lipophilic drugs and provides insight into the design and development of drug products for the reader.

7.2 Absorption Pathways of Lipophilic Drug via Lipid-Based Formulations

A possible mechanism for the enhanced uptake of the drugs from the SEDDS type of formulations in the small intestine is depicted in Fig. 7.1 (Gao and Morozowich 2007a). All relevant scientific findings to support this hypothesized absorption scheme are given in Gao and Morozowich (2007a) with details.

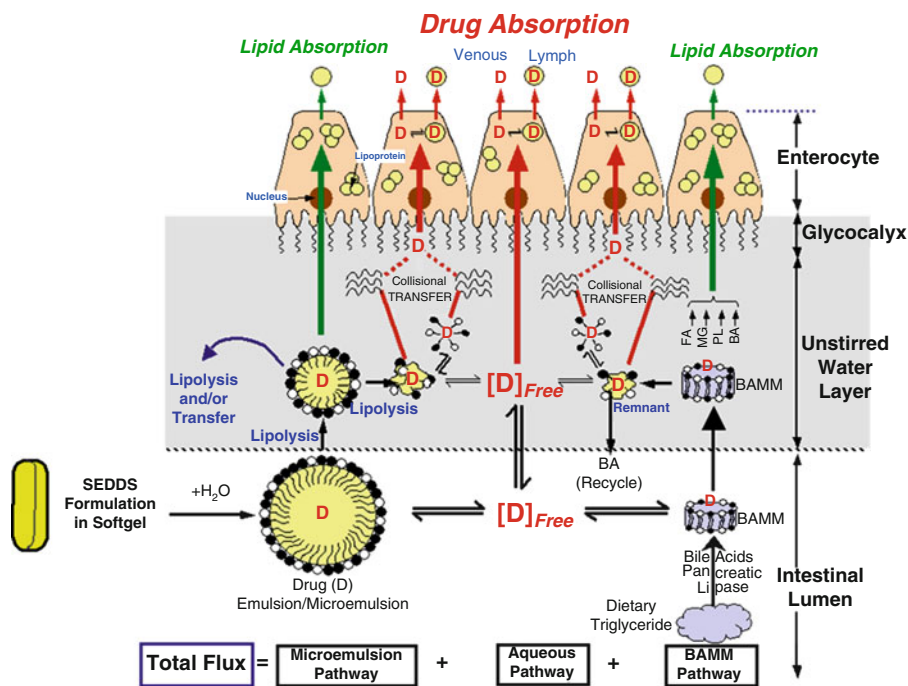

Fig. 7.1 Proposed scheme for the enhanced oral absorption seen with poorly soluble lipophilic drugs in SEDDS formulations. The drug (D) from the SEDDS formulation could be presented to the intestinal enterocyte brush border region by either simulating or equilibrating with the BAMM pathway with collisional transfer to the brush border or by the aqueous diffusional pathway

Drugs with water solubility of about 1–10 $\mu\text{g/mL}$ frequently show incomplete oral absorption. However, there are many other extremely insoluble, highly lipophilic compounds that have solubility orders of magnitude less than 1–50 $\mu\text{g/mL}$ and are efficiently absorbed orally.

The pioneering work of Borgstrom et al. and later, Carey et al., as well as many others contributed to the finding that the bile acid mixed micelle (BAMM) in the fed state and the bile acid (BA) micelle in the fasted state constitute the endogenous surfactant system that is responsible for the delivery or presentation of extremely lipophilic drugs to the enterocyte brush border region.

Cholesterol with a clogP of 12 and a water solubility of ~ 10 ng/mL is efficiently absorbed from the intestine by presentation of cholesterol dissolved in the BAMM particles to the enterocyte brush border mucosa with subsequent collisional transfer to the glycocalyx. Other extremely insoluble and lipophilic compounds are absorbed more efficiently in the fed state than in the fasted state where the BAMM is present. The BAMM system is more effective than the BA system because of the higher micellar concentration in the fed as compared to the fasted state. It is worth noting

that the delivery of cholesterol from the BAMB to the enterocyte surface occurs via collisional transfer.

Based on the brief summary described above, it appears that drugs could be delivered to the intestinal enterocyte brush border region by the aqueous diffusional pathway as well as by the BA/BAMB pathway. SEDDS formulations can generate emulsions (E) or microemulsions (MEs) upon contact with water and they can undergo size reduction through a number of phenomena such as the hydrolytic action of the pancreatic or membrane-bound enzymes or by the removal of the E/ME components by collisional transfer with other lipophilic materials in the intestine. Thus, drugs in the E/ME or the remnant E/ME either can be rapidly released into the aqueous medium or can undergo collisional transfer to the enterocyte brush border.

Figure 7.1 depicts a plausible scheme for the presentation of poorly soluble lipophilic drugs in SEDDS formulations to the intestinal enterocyte brush border by:

- The aqueous pathway, or by
- Equilibrating with the BA/BAMB pathway, or by
- Mimicking the BA/BAMB pathway

After absorption into the enterocyte, the drug could diffuse across the enterocyte or, if the drug is highly lipophilic, it could partition into the chylomicrons in the fed state with subsequent transfer to the lymphatics and ultimately to the systemic venous circulation (Porter et al. 2007). Moderately lipophilic drugs could escape from the chylomicrons by partitioning or collisional transfer with entry into the venous system. The implication from the proposed absorption scheme in Fig. 7.1 is that the selection of lipid excipients in the SEDDS formulation could have a profound effect on the extent of oral bioavailability by affecting the delivery of the drug to the enterocyte brush border or by affecting the transport across the enterocyte.

Supersaturatable S-SEDDS formulations are designed to contain a reduced amount of surfactant along with the use of polymeric precipitation inhibitor (PCI) in order to generate a supersaturated drug solution upon contact with water, and the resulting supersaturated state is to be maintained sufficiently long to achieve enhanced absorption. S-SEDDS formulations of poorly water-soluble drugs offer a great potential to improve the rate and extent of absorption of the drug along with a better toxicity/safety profile of the product (Gao and Morozowich 2005, 2007b). This is primarily attributed to the less amount of surfactant in the vehicle as compared to that of corresponding conventional SEDDS formulations of the same drug.

The supersaturated state generated from appropriate supersaturatable formulations has been demonstrated to significantly improve intestinal absorption of poorly soluble drugs (Gao and Morozowich 2005, 2007b). This is presumably attributed to enhanced presentation of the drug to the enterocyte brush border region by the aqueous pathway shown in Fig. 7.1 due to the increased free drug concentration achieved by supersaturation and along with enhanced presentation of the drug to the enterocyte brush border by mimicking or equilibrating with the BA/BAMB pathway.

7.3 Characterization of Self-Emulsifying Lipid Formulations and Understanding Key Variables Upon Drug Absorption

There are a number of physicochemical attributes of SEDDS formulations that are important with respect to oral bioavailability. Although several *in vitro* test methods have been applied to characterize the performance of SEDDS formulations (Gao and Morozowich 2005, 2007a, b; Dressman et al. 2007; Humberstone and Charman 1997; Vonderscher and Meinzer 1994; Nazzal et al. 2002; Shah et al. 1994; Porter and Charman 2001; Odeberg et al. 2003), there is a lack of consensus concerning the methodology and the test methods. Poor correlations between *in vitro* characterizations and *in vivo* bioavailability have been observed, particularly for lipid-based systems containing a significant amount of digestible lipids such as long-chain di- and triglycerides. One of the possible reasons of such poor correlations is attributed to the inadequacy of the *in vitro* tests used in characterization does not simulate the chemical and physical environment that the lipid formulations encounter.

During our exploration and development of SEDDS formulations, *in vitro* test methods were developed and they served as a guide in formulation screening and optimization. There are four types of *in vitro* performance measurements for an SEDDS formulation described below:

- Emulsification spontaneity
- Dispersibility (i.e., particle size)
- Solubilization of the drug and potential of drug precipitation
- Lipid lipolysis and its effect upon drug solubilization

Three attributes of SEDDS formulations are conceptually illustrated in Fig. 7.2, and these attributes can be evaluated *in vitro* with appropriate test methods (Gao and Morozowich 2007a). Emulsification kinetics of a given SEDDS formulation in the aqueous medium is important, and a number of test methods have been reported (Nazzal et al. 2002; Shah et al. 1994; Porter and Charman 2001; Odeberg et al. 2003). As shown in Fig. 7.2, the slope of the release profile from the SEDDS formulation observed at the initial stage (e.g., the first 30 min) with the use of a conventional drug-release test is indicative of its emulsification spontaneity. The emulsification spontaneity of the SEDDS formulation to yield an emulsion or a microemulsion upon contact with an aqueous medium may affect the drug-release kinetics and therefore, the extent of drug absorption.

The dispersibility of the SEDDS formulation is evaluated by the particle size of the resulting emulsion or microemulsion that is generated upon dilution with water. This is considered as a key factor in the performance of SEDDS formulations since the droplet size may determine the rate and extent of drug-release *in vivo* and subsequent absorption (Shah et al. 1994). Although the emphasis on the generation of a microemulsion is inherent in this technology, the importance of particle size on the exposure of poorly soluble drugs has not been clearly established.

The extent of drug solubilization in the test medium upon the release from the SEDDS formulation may change and the drug may precipitate in the test medium.

Fig. 7.2 In vitro characterization of the key attributes of an SEDDS formulation is conceptually illustrated: (a) emulsification spontaneity, (b) dispersibility (i.e., microemulsion/emulsion droplet size), and (c) the extent of solubilization in a test medium

As indicated in Fig. 7.2, the extent of drug solubilization as a function of time can be conveniently determined in a biorelevant in vitro release test. It is worth noting that the choice of a test medium with appropriate composition and volume is a crucial factor here, since the solubilization capacity of the test medium (e.g., sink vs. nonsink condition) will inevitably affect the extent of drug solubilization and also its precipitation process.

As described in absorption scheme in Fig. 7.1, lipid lipolysis may have a profound effect upon drug solubilization and potential enhancement to the drug absorption by the BAMB pathway. In vitro lipid digestion models may allow systematic differentiation of candidate lipid formulations with different type and amount of lipid for a given candidate drug (Porter and Charman 2001).

7.3.1 Assessment of Emulsification Spontaneity and Emulsion Particle Size

Drug X is highly lipophilic with an intrinsic LogP of ~ 7 , an MW of ~ 600 , and an aqueous solubility of $\sim 5 \mu\text{g/mL}$ in the physiologically relevant pH range from pH 2 to 7 (Gao and Morozowich 2007a). Since a high dose of Drug X was anticipated, SEDDS formulations containing 300 mg/g Drug X (free acid form) were developed (Gao and Morozowich 2007a).

Ethanol (EtOH) and propylene glycol (PG) are commonly employed as cosolvents in SEDDS formulations. These solvents aid in the emulsification spontaneity of SEDDS formulations of Drug X. Release profiles from four SEDDS formulations

Fig. 7.3 Effect of EtOH concentration (mg/g) on the release profile of Drug X from the SEDDS formulations containing 73 mg/g propylene glycol (PG)

with various ethanol concentrations from 0 to 100 mg/g, while keeping the PG level constant (73 mg/g), are shown in Fig. 7.3. The initial slope and the shape of the drug-release profiles indicate that an increase in the ethanol concentration gives an increase in the emulsification spontaneity and an increase in the subsequent extent of release. Drug-release profiles from the other four SEDDS formulations containing various PG concentrations ranging from 0 to 75 mg/g and a constant EtOH level of 100 mg/g are shown in Fig. 7.4. Drug-release or emulsification spontaneity of the SEDDS formulation appears to be less sensitive to the PG levels than to the EtOH levels.

The effect of dispersibility of the 300 mg/g Drug X SEDDS formulation on oral bioavailability was evaluated with two different approaches (Gao and Morozowich 2007a). While the first approach was to keep the formulation composition unchanged, but the droplet size, upon dilution of the formulation with water, was varied by mechanical reduction of the particle size using a microfluidizer. Dilution of the initial 300 mg/g Drug X SEDDS formulation resulted in spontaneous generation of an emulsion with a mean particle size of $\sim 1 \mu\text{m}$. A portion of the emulsion was passed through the microfluidizer twice with a setting of 3,500 psi and the resulting mean particle size of the emulsion was $\sim 220 \text{ nm}$. Both the initial and the microfluidizer-processed emulsions were administered to rats. The absolute oral bioavailability of Drug X was estimated to be $21\% \pm 3\%$ for the crude emulsion and $53 \pm 31\%$ for the processed emulsion (Table 7.1). This suggests approximately a 2.5-fold enhancement attributable to droplet size reduction of the emulsion.

Fig. 7.4 Effect of propylene glycol (PG) concentration (mg/g) on the release profile of Drug X from the SEDDS formulations containing 100 mg/g EtOH

Table 7.1 Composition of the 300 mg/g Drug X SEDDS formulations, their properties, and bio-availability in fasted rats after an oral dose of 20 mg/kg

| | | |
|---------------------------------------|------------------|-------------------------|
| | Drug X | 300 |
| | EtOH/PG (1:1) | 200 |
| | Cremophor EL | 425 |
| | GDO/GMO (8:2) | 75 |
| Formulation composition (mg/g) | | |
| Processing | Initial emulsion | Microfluidized emulsion |
| Droplet size \pm SD (nm) | \sim 1,000 | 221 \pm 115 |
| No. of rats dosed | 8 | 6 |
| Mean AUC/dose [μ g h/mL]/(mg/kg) | 2.7 \pm 0.4 | 6.8 \pm 4.0 |
| Mean C_{max} \pm SD (μ g/mL) | 14.1 \pm 4 | 33.9 \pm 19 |
| Absolute oral F% \pm SD | 21 \pm 3 | 53 \pm 31 |

The two predispersed emulsions differing in particle size were obtained from the same lot of the SEDDS formulation wherein a portion of the lot was processed with the microfluidizer

In the second approach to evaluate the influence of the particle size of the SEDDS formulations on oral exposure of Drug X, the oral bioavailability of the formulations with and without amine was determined and compared (Gao and Morozowich 2007a). The presence of a small amount of amine can significantly reduce the particle size of the formulation to \sim 150 nm upon dilution with water due to ion-pairing between the amine and acidic drug. The in vivo pharmacoki-

Fig. 7.5 Summary of the relative oral bioavailability of the 300 mg/g Drug X SEDDS formulations in the presence and absence of an amine (either DEA or Tris) in the rat, dog (cross-over), and human (cross-over)

netic results of these paired 300 mg/g Drug X SEDDS formulations (the same composition but differing only with respect to the presence or absence of an amine) were obtained in rats, dogs, and humans. The relative oral bioavailability of Drug X from these paired SEDDS formulations is normalized and plotted in Fig. 7.5. The relative oral bioavailability of Drug X in rats (noncross-over), dogs (cross-over), and humans (cross-over) was consistently improved by approximately 2–3 fold by the simple addition of 1.5–5.0% (w/w) of an amine in the corresponding SEDDS formulation, resulting in microemulsions of ~150 nm. (Gao and Morozowich 2007a) These in vivo results consistently demonstrate that the formation of microemulsions from the 300 mg/g Drug X SEDDS formulation upon dilution is crucial in improving the oral absorption of Drug X in animals and humans.

7.3.2 *In Vitro* Drug Solubilization and Supersaturation

Previous studies reported a biphasic test method that involves simultaneous “dissolution–partition” kinetics (Hoa and Kinget 1996; Ngo et al. 1997; Grundy et al. 1997, 1998; Vangani et al. 2009; Shi et al. 2010). The biphasic dissolution system developed in our lab is shown in Fig. 7.6. For poorly water-soluble drugs, a nonsink, biorelevant aqueous medium is highly desirable, while the organic phase acts as a sink condition. A biphasic test method may offer two major advantages

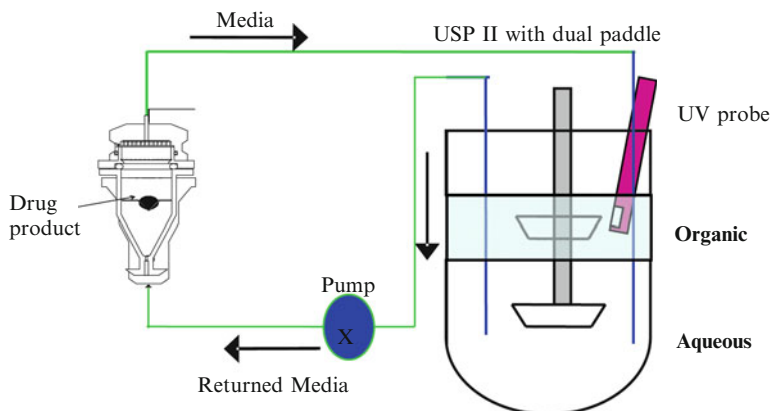

Fig. 7.6 Schematic diagram of biphasic test system

over single, aqueous phase test systems. First, due to partitioning into the organic phase, the dissolution profile of the dosage forms in the aqueous phase from the biphasic system may differ from that observed when only an aqueous phase is involved. Second, as the free drug concentration in the aqueous phase is the sole driving force for partitioning, the drug concentration profile accumulated in the organic phase could be used to differentiate different formulations.

Our study examined three celecoxib (CEB) formulations of distinctly different attributes with the use of the biphasic in vitro test method (Shi et al. 2010). These formulations included a commercial Celebrex[®] capsule, a solution formulation (containing cosolvent and surfactant), and an S-SEDDS formulation, and their pharmacokinetic data in human subjects have been reported.

Release profiles of CEB observed in the aqueous phase from the solution and S-SEDDS formulation are comparable in the single-phase dissolution test as well as in the biphasic test (Fig. 7.7a, b). In contrast, corresponding concentrations of CEB observed in the octanol phase differ significantly (Fig. 7.8). This is presumably attributed to their difference in the free drug concentration obtained in the aqueous phase from these two formulations. Due to the high surfactant level in the solution formulation (i.e., CEB:Tween 80 = 1:1.5, w/w), CEB released from the solution formulation is mostly associated with surfactant micelles in the dissolution medium and, therefore, a lesser amount of free CEB is present in the aqueous phase. In contrast, a significantly lower level of surfactant was employed in the S-SEDDS formulation (i.e., CEB:Tween 80 = 1:1, w/w) and this leads to the generation of a highly supersaturated state of CEB.

As compared to Celebrex[®] capsule, solubilization of CEB via surfactant micelles in the aqueous phase from the solution formulation did not lead to an increase of drug partitioning into the octanol phase (Fig. 7.8). These two formulations yield comparable CEB concentration profiles in the octanol phase. This agrees with the relative AUC of CEB observed in the human subjects. It has been well recognized

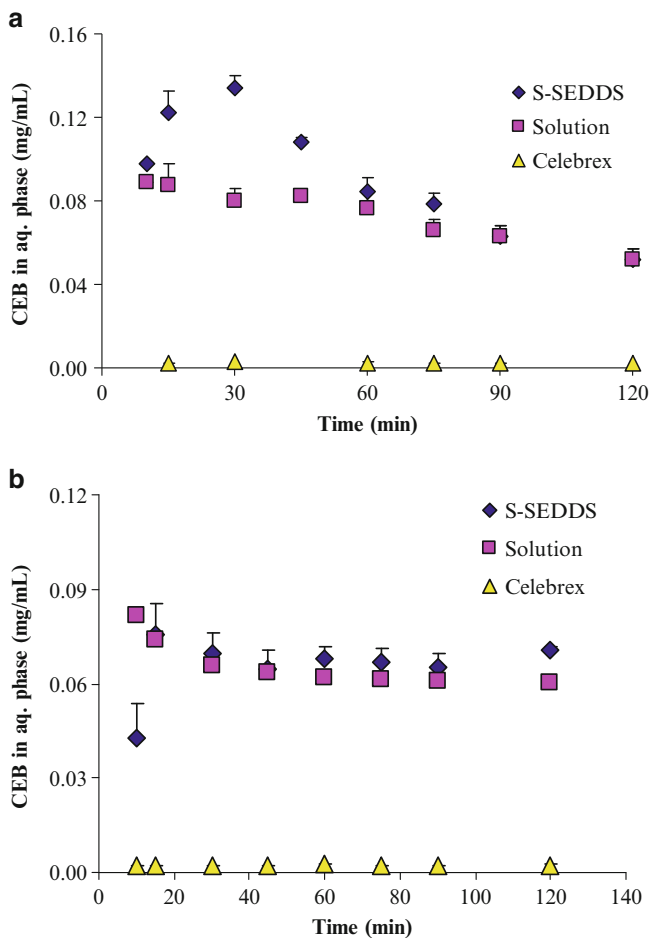

Fig. 7.7 (a) CEB release profiles from the three formulations in the aqueous phase from the biphasic test and (b) CEB release profiles from the three formulations obtained from the single-phase dissolution test under nonsink conditions

that micellar solubilization of hydrophobic drugs could result in decreased in situ permeation and reduced oral bioavailability. The pharmacokinetic profiles observed in human subjects from the three CEB formulations are shown in Fig. 7.9 and are consistent with this analysis (Shi et al. 2010).

CEB concentration–time profiles observed in the aqueous phase from the single-phase dissolution test and the biphasic test are found to bear no relationship with the relative AUCs in human subjects. In contrast, a rank order correlation is obtained

Fig. 7.8 CEB release profiles from the three formulations in the octanol phase obtained from the biphasic test

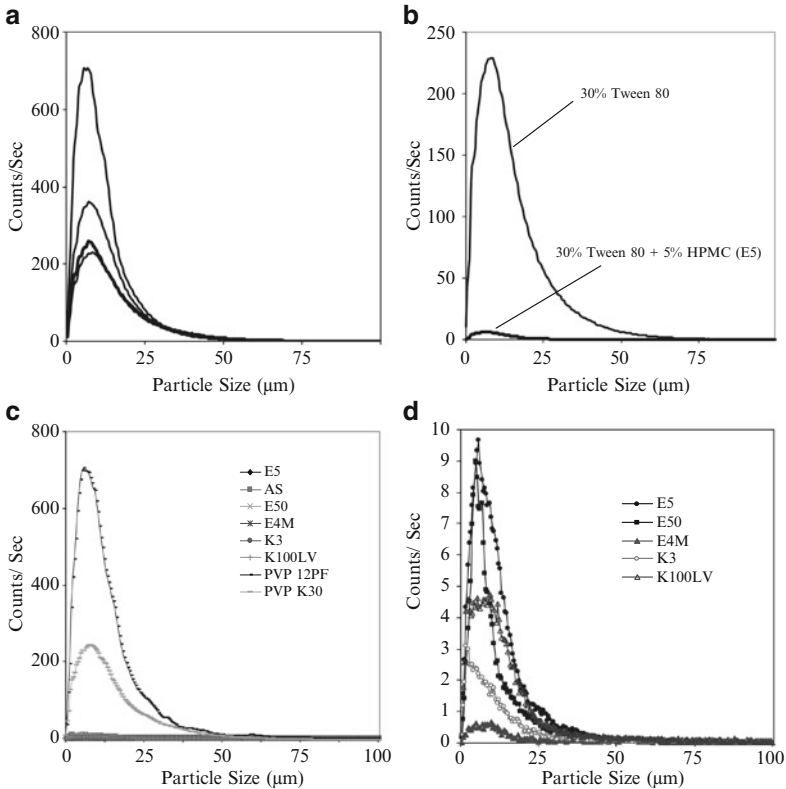

Fig. 7.9 Mean PSD profiles observed at $t=60$ min from (a) SEDDS formulations (without PPI) containing 10%, 20%, 30%, and 40% (w/w) Tween 80, respectively; (b) SEDDS formulations containing 30% (w/w) Tween 80 with and without 5% HPMC(E5); (c) S-SEDDS formulations with 5% HPMC of -E5, -E50, -E4M, -K3, -K100, or 5% PVP of -12PF and K30 or 5%, HPMCAS, and (d) same data plotted in (c) but with a more sensitive Y scale

among the three test formulations between their in vitro AUC values of CEB obtained from the octanol phase and the in vivo AUC (or C_{\max}) values in human subjects. As the partitioning of dissolved drug from the aqueous phase into the organic phase closely mimics the absorption process in vivo, CEB concentrations observed in the octanol phase appear to agree with the human bioavailability data with in vitro–in vivo relationship (IVIVR) (Shi et al. 2010). Preliminary examination of three CEB immediate release formulations indicates that the biphasic test method permits a cross-comparison of formulation attributes associated with different approaches and provides sufficient discrimination for formulation selection and optimization.

7.3.3 Characterization of Drug Precipitation Kinetics

A key consideration in design and development of an S-SEDDS formulation is based on the generation and maintenance of a supersaturated state in vivo for a sufficiently long time, permitting improved absorption in the GI tract. However, incomplete solubilization of the drug may inevitably result in precipitation upon dilution of the formulation with aqueous media.

While PCI is usually used to prevent or retard drug precipitation, the effectiveness of PCI associated with other key formulation variables needs to be assessed experimentally.

In order to characterize the drug precipitation process, a fast and reliable estimation of the formation, growth, aggregation, and attrition of particles in the system is crucial. FBRM is a desirable measurement technology that conducts in situ particle characterization. Its detection principle is discussed in detail in the scientific literature (Barrett and Gleannon 1999). We utilized FBRM to determine the effect of PCI (e.g., regarding its type and concentration) in the formulation upon drug precipitation kinetics (Gao et al. 2009).

AMG 517 is a potent and selective VR1 antagonist that was being developed for the treatment of acute and chronic pain (Gao et al. 2009). This drug candidate possesses a high hydrophobicity ($c\text{LogP}=5.1$) and extremely low intrinsic water solubility ($\sim 0.05 \mu\text{g/mL}$). Low and highly variable in vivo exposures of AMG 517 in monkeys were observed from a variety of formulation approaches in preclinical evaluations.

The concentration of the surfactant, Tween 80, in the S-SEDDS formulation was considered to be a critical formulation variable since its amount dictated the initial degree of solubilization of AMG 517 upon mixing the formulation with water and, therefore, the supersaturated state (Barrett and Gleannon 1999). In order to determine the influence of the concentration of Tween 80 upon AMG 517 precipitation kinetics, a series of SEDDS formulations containing Tween 80 varying from 10, 20, and 30 to 40% (w/w) were characterized. All particle size distribution (PSD) profiles observed from these SEDDS formulations (without PCI) at $t=60$ min. are shown in Fig. 7.9a for comparison. The significant variation of the peak counts/sec. in these

PSD profiles accompanying the variation of Tween 80 concentration reveals that it indeed dictates AMG 517 precipitation kinetics. For instance, the SEDDS formula containing 10% Tween 80 exhibited a PSD peak of ~ 720 counts/s around $\sim 10 \mu\text{m}$ (Fig. 7.9a). Upon increasing the Tween 80 concentration to 20%, the PSD profile shows the same distribution but a significantly lower peak value of ~ 380 counts/s. Further increasing Tween 80 concentrations to either 30 or 40%, the shape of the PSD profiles was not affected and lower peak values (e.g., ~ 240 counts/s) were observed. There was essentially no difference in precipitation kinetics between 30% and 40% Tween 80, suggesting an optimal concentration of 30% in the S-SEDDS formulation.

In situ PSD profiles from the S-SEDDS formulations indicate that incorporation of a small amount of 2–5% HPMC (E5) effectively suppresses AMG 517 precipitation. This is clearly evidenced by the comparison of the PSD profiles between a pair of the SEDDS formulations containing 30% Tween 80 with and without HPMC (E5). As shown in Fig. 7.9b, the S-SEDDS formulation with 5% HPMC (E5) shows a PSD profile with its peak shifting to a slightly smaller size of $\sim 7 \mu\text{m}$ and less than 10 counts/sec. at $t=60$ min. while the SEDDS formulation (without PCI) shows a peak around $10 \mu\text{m}$ with ~ 230 counts/s. The PSD profiles shown in Fig. 7.9c suggest that incorporation of 5% PVP in the S-SEDDS formulation, either 12PF, low MW PVP or K30, high MW PVP, appears ineffective while HPMCAS and HPMC (both the E and the K series) were highly effective.

Figure 7.9d closely examines the PSD profiles observed from S-SEDDS formulations with 5% HPMC at different viscosity grades including -E5, -E50, -E4M, -K3, and -K100. The PSD data observed are in excellent agreement with the apparent in vitro AMG 517 concentration–time profiles from the same formulations (Gao et al. 2009). The former test measures the precipitation kinetics of the drug by counting the number of precipitates and its PSD profiles, while the latter test provides a quantitative estimation of the apparent drug concentration remaining in the test media. The two in vitro characterizations for AMG 517 S-SEDDS formulations are complementary to each other and these observations with time-dependent feature are in good agreement. These two in vitro tests are proven appropriate tools for S-SEDDS formulation screening and optimization.

7.3.4 *In Vitro Lipolysis and Drug Solubilization*

The major purpose for the development of the dynamic in vitro lipolysis model is correlating the in vitro information of various drug lipidic vehicle combinations to the resultant in vivo absorption profile of the tested drug (Dahan and Hoffman 2008; Fatouros and Mullertz 2008). Although different models of lipolysis developed for studies of drug solubilization upon lipid digestion have been published (Dahan and Hoffman 2008; Fatouros and Mullertz 2008), the current models only consider intestinal lipid digestion. A representative lipolysis model is shown in Fig. 7.10 (Dahan and Hoffman 2008).

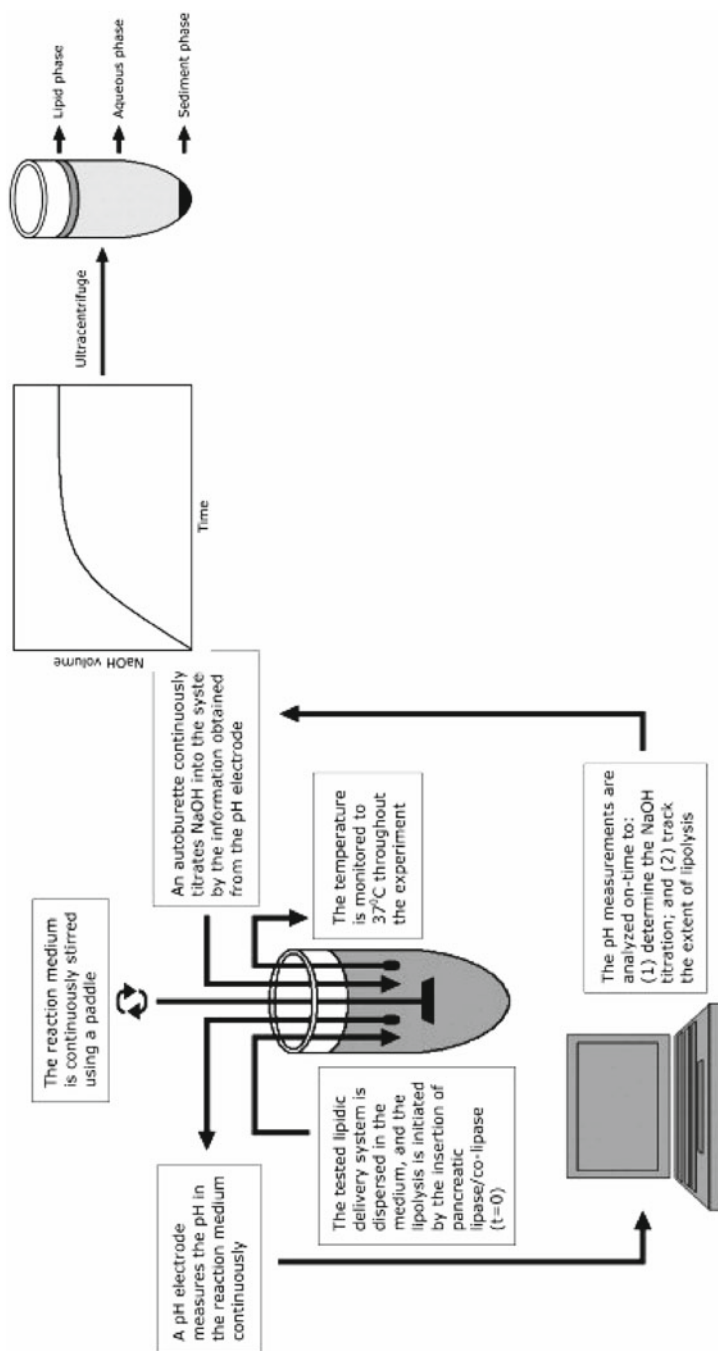

Fig. 7.10 Experimental apparatus of dynamic in vitro lipolysis model from Dahan and Hoffman (2008)

The effect of an SEDDS formulation composition involving lipid, surfactant, and cosolvent on the solubilization capacity of danazol during *in vitro* digestion and correlation with *in vivo* exposure in beagle dogs was explored by Cuine et al. (2007). Lipolysis studies of SEDDS containing 60, 37.5, 18, and 0% lipid showed that a reduction in relative lipid content resulted in a significant loss of solubilization capacity of the colloid species formed following the digestion process. Consistent with *in vitro* lipolysis results, *in vivo* oral administration of such danazol SEDDS to beagle dogs revealed a decrease in oral bioavailability, as the quantity of lipid present in these formulations was reduced and the amount of surfactant and/or cosolvent increased. This study revealed that the surfactant, Cremophor EL, due to its susceptibility to lipase-mediated digestion, may result in the production of colloid species with reduced solubilization capacity following the lipolysis process.

Dahan and Hoffman (2006) investigated the distribution and solubilization pattern of progesterone across the different phases of the *in vitro* lipolysis model resulting from LCT-, MCT-, and SCT-based lipidic systems, followed by *in vivo* evaluation. The *in vitro* lipolysis study indicated a performance rank order of MCT > LCT > SCT by the percentage of progesterone dose solubilized in the aqueous phase following the lipolysis process. The *in vivo* bioavailability of progesterone from the MCT lipid was fourfold higher in comparison to the LCT-based lipidic system and 11-fold higher than the SCT. These results correlate well with the results of *in vitro* lipolysis study with the same rank order observed. Furthermore, an excellent correlation was obtained between the percentage of progesterone dose that was solubilized in the aqueous phase of the *in vitro* lipolysis medium and the *in vivo* AUC values of these formulations upon oral administration in rats.

Dahan and Hoffman (2007) recently investigated the distribution and solubilization pattern of dexamethasone and griseofulvin across the different phases of the *in vitro* lipolysis model resulting from LCT-, MCT-, and SCT-based lipid systems, followed by *in vivo* evaluation of these formulations. For dexamethasone, the *in vitro* lipolysis results demonstrated that the three lipids did not differ in its solubilization capacity in the aqueous phase. In contrast, for griseofulvin, the *in vitro* lipolysis results showed significant differences between these formulations (Dahan and Hoffman 2007). MCT lipid led to high amounts of solubilized drug in the aqueous phase (>95%), while the LCT lipid resulted in a smaller amount, and the SCT proved the lowest (Fig. 7.11a). All three lipid formulations proved to be advantageous over the control, an aqueous suspension. A similar trend was confirmed by the *in vivo* PK study. As shown in Fig. 7.11b, the exposure of griseofulvin was directly related to the nature of the lipid component, showing the rank order MCT > LCT > SCT > water. An excellent correlation (Fig. 7.11c) between the percentage of griseofulvin dose that was solubilized in the aqueous phase of the *in vitro* lipolysis medium and the *in vivo* AUC values upon oral administration of these four formulations was observed.

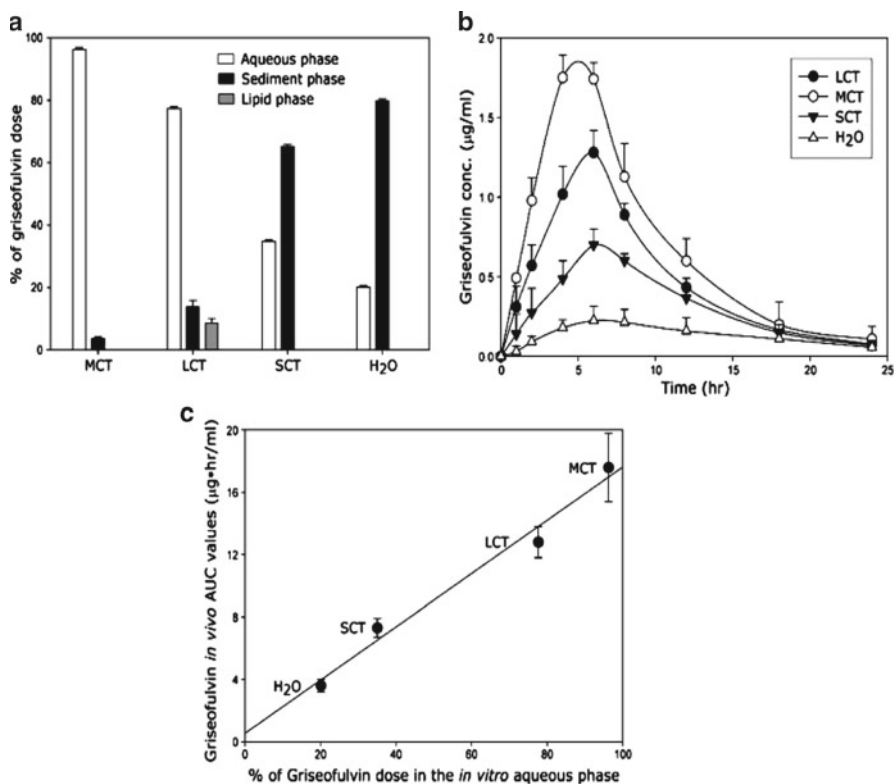

Fig. 7.11 (a) Distribution of griseofulvin in the aqueous phase, sediment, and lipid phase, (b) Plasma concentration–time profiles of griseofulvin and (c) IVIVC between solubilized griseofulvin in the aqueous phase upon in vitro lipolysis and the in vivo AUC

7.4 Conclusions

Lipid-based vehicles, especially microemulsions, possess immense potential in drug delivery applications and have been shown to provide increase in solubilization, improved bioavailability, reduced variability from food effects on bioavailability, protection for labile drugs, and controlled drug-release rates. However, for the full commercial application of these systems considerably more work needs to be done to understand their key attributes and the in vivo absorption process.

These four in vitro test methods employed in the SEDDS and S-SEDDS formulation development turned out to be qualitatively and/or quantitatively predictive for the in vivo performance of these formulation candidates. Lead formulations with poorly water-soluble drugs could be reliably screened out and further optimized using these methods, with fundamental understanding of key attributes responsible

for improved bioavailability. This *in vitro* characterization in combination with appropriate *in vivo* evaluation presents a very effective and practical approach to facilitate the rational selection of excipients and maximize the critical attributes of formulations with confidence and high success probability.

Further, more mechanistic studies should be encouraged to gain a deep understanding of the role of surfactants and lipids in the drug solubilization and absorption pathway and the complex interactions between the lipid excipient, the drug, and the physiological environment. In this regard, the dynamic *in vitro* lipolysis of lipidic formulations and its relevance to *in vivo* exposure are highly valuable as it may reveal the underlying mechanism responsible for increased bioavailability of poorly water-soluble drugs through these formulations. It is worth emphasizing that the *in vitro* experimental methods for lipid-based formulations described in this review are intended to simulate and/or elucidate the complex process *in vivo* and these methods are considered to be still in their infancy. Needless to say, further development and optimization of such methods and a deep understanding of the key attributes of the candidate formulations for a given drug are crucial to the success in design and development of lipid-based formulations.

Method Capsule 1

Application of In Vitro Lipolysis Model to Guide Lipid Formulation Development and Establish Its Relevance to In Vivo Bioavailability in Rats

Based on the method reported by Dahan and Hoffman (2007)

Objective

- To investigate the impact of different lipid-based formulations of lipophilic drugs on *in vitro* solubilization and intestinal *ex vivo* permeability process.

Equipment and Reagents

- Dexamethasone, and micronized griseofulvin.
- Triacetin, taurocholic acid, pancreatin, L-alpha-phosphatidylcholine, triglycerides of caprylic/capric acid, and Captex 355.
- Ethanol, methanol, acetonitrile, water, n-hexane, potassium chloride, magnesium chloride, and sodium chloride.
- Ussing diffusion chambers.

Method

- *In vitro* lipolysis – the experimental medium (e.g., 35.5 mL of digestion buffer (50 mM Tris maleate, 150 mM NaCl, and 5 mM CaCl₂, pH 6.8) containing 5 mM taurocholic acid and 1.25 mM L-alpha-phosphatidylcholine) was continuously stirred (100 rpm) and held at 37°C. One gram of the tested formulation (e.g., a suspension containing 5 mg of the drug, stirred and gently

heated to 37°C, freshly prepared 30 min before experiment) was then dispersed in the medium and stirred. A total of 3.5 mL of fresh pancreatin extract was added to the medium. The pH was maintained at 6.8. This allowed characterization of propagation of the lipolysis process on the dynamic influence on solubilization of the coadministered drug.

- Ex vivo permeation – Permeability was determined by a modified Ussing diffusion chamber. A small section of the intestine of male Wistar rats is clamped between two chambers filled with buffer. The donor cell contains drug molecules. The medium from the in vitro lipolysis experiment was added to the mucosal side of the Ussing chambers. This medium contained the digestion buffer, the drug molecules in the different states, and the lipolytic products liberated from the tested lipidic vehicle. The integrity of epithelial tissue was monitored by transepithelial electrical resistance.

Results

- The dynamic in vitro lipolysis experiments indicated an equivalent performance of the different formulations for dexamethasone, and a performance rank order of MCT > LCT > SCT > H₂O for griseofulvin.
- The in vivo bioavailability of both drugs correlated well with the in vitro data, i.e., LCT = MCT = SCT for dexamethasone and MCT > LCT > SCT > H₂O for griseofulvin.
- The ex vivo permeability studies of both drugs indicate the SCT formulation caused enhanced permeability; however the enhanced permeability appears showing no correlation with in vivo bioavailability.
- The in vitro lipolysis model was found to be useful in the intelligent optimization of oral lipid formulations for lipophilic drugs.

Method Capsule 2

Investigation of the Effect of Surfactant and Lipid in Self-Emulsifying Formulations Upon Oral Bioavailability of Danazol in Beagle Dogs

Based on the method reported by Cuine et al. (2007)

Objective

- To investigate the impact of change in proportions of lipid, surfactant, and cosolvent on the solubilization capacity and the bioavailability of self-emulsifying formulations of danazol.

Equipment and Reagents

- Danazol.
- Soybean oil, Cremophor EL, PEG 400, sodium taurodeoxycholate, porcine pancreatin, Maisine 35-1, and lecithin.

- USP II dissolution apparatus.
- Malvern Zetasizer 3000.

Method

- Dispersion studies were performed in 250 mL of 0.1 N HCl at 37°C using USP II dissolution apparatus. One gram formulation was added to dissolution media and drug dissolution was measured over 1 h. The mean particle size of the dispersed emulsion/microemulsion droplets in the dissolution media was measured by photon-correlation spectroscopy..
- In vitro digestion experiments were performed by dispersing 1 g self-emulsifying lipid-based formulation (containing danazol at 80% of its saturated solubility in the formulation) in 36 mL of digestion buffer containing 5 mM sodium taurodeoxycholate and 1.25 mM phosphatidylcholine.
- Bioavailability studies were conducted in male beagle dogs.

Results

- A rank-order correlation was observed between drug concentration profiles obtained during in vitro digestion and the in vivo performance of self-emulsifying formulations of danazol.
- Inclusion of high quantities of Cremophor EL and co-solvent in formulations in order to facilitate rapid emulsification and the production of small particle size dispersions may lead to a reduction in oral bioavailability. Higher quantities of long-chain lipid effectively prevent drug precipitation in vivo and lead to higher oral bioavailability.
- Non-ionic surfactants such as Cremophor EL may be susceptible to lipase-mediated digestion and that this in turn may affect their capacity to enhance solubilization in vivo.

Method Capsule 3

Characterization of S-SEDDS Formulation of Celecoxib by In Vitro Biphasic Test and Its Relevance to In Vivo Absorption in Humans

Based on the method reported by Shi et al. (2010)

Objective

- To characterize drug release profiles of three formulations of celecoxib (CEB) including a S-SEDDS formulation by an in vitro biphasic test and establish the relevance of the in vitro profiles to in vivo absorption in human subjects.

Equipment and Reagents

- Celecoxib, marketed product (Celebrex®).
- Ethanol, PEG400, PVP-12 PF, HPMC (E5), oleic acid, Tween 80, octanol.

- Gelatin capsule (size 1).
- USP II dissolution apparatus with a vessel containing two phases: aqueous phase and octanol phase. The aqueous phase was 250 mL 80 mM phosphate buffer and the octanol was 200 mL. A dual paddle was used at 75 rpm.
- USP IV dissolution apparatus (a flowcell) was connected to the USP II vessel through a closed loop with the aqueous dissolution medium circulated at 30 mL/min.

Method

- CEB S-SEDDS formulation was prepared by mixing the drug in the vehicle containing PEG 400, oleic acid and Tween 80 under gentle heating (~ 50°C) and vortexing to yield a clear solution.
- Pharmacokinetic study conducted in human volunteers at a dose of 200 mg as reported previously in the ref therein.

Results

- The biphasic test results reveal that the S-SEDDS formulation of CEB rapidly yields and sustains a supersaturated state as compared to the marketed capsule and suspension formulation. The high mean C_{max} and AUC observed in human subjects from the S-SEDDS formulation is attributed to the supersaturated state of CEB.
- In vitro CEB conc-time profiles observed in the aq. phase (with and without the octanol phase) are found to bear no relationship to the in vivo AUC in human subjects.
- Good in vitro-in vivo relationship (IVIVR) is obtained between the CEB conc. in the octanol phase at t = 2 hrs of the three formulations and their mean in vivo AUC and C_{max} values observed in human subjects.
- The biphasic test method appears an effective tool for screening and optimizing formulations of BCS II drugs.

Method Capsule 4

Optimization of AMG517 S-SEDDS Formulation with Polymeric Precipitation Inhibitors

Based on the method reported by Gao et al. (2009)

Objective

- To develop S-SEDDS formulation of an extremely low water solubility drug AMG517 and evaluate its bioavailability in monkeys.
- To investigate the effectiveness of different polymeric precipitation inhibitors (PPI) upon sustaining a supersaturated state of AMG517 in the aqueous medium by FBRM spectroscopy.

Equipment and Reagents

- AMG517.
- PEG400, HPMC (E5, E50, E4M, K3, K100), PVP (12PF, K30), HPMCAS, Tween 80, Capmul MCM.
- Gelatin capsule (size 1)
- In vitro dissolution apparatus containing 100 ml simulated gastric fluid (e.g., 0.01M HCl) with a peddle speed of 100 rpm.
- FBRM probe.

Method

- Multiple S-SEDDS formulations of AMG517 were prepared by varying the type and molecular weight of PPI. The formulation mixture was mixed at ~ 50 °C, and the drug was dissolved by vortexing. PPI powders were suspended in the liquid formulation by vortexing.
- The S-SEDDS formulation was filled into size 1 capsules and orally administered to Cynomolgus monkeys at a dose of 12.5 mg.
- In situ FBRM spectroscopy was used to characterize AMG517 precipitation process (e.g., to determine the number of precipitate particles and the dynamic particle size distribution against time) after the S-SEDDS formulation was mixed with the dissolution medium.

Results

- The level of Tween 80 in AMG517 S-SEDDS formulation dictates the initial solubilization and also the degree of supersaturation of AMG517 upon mixing with water and, therefore, the drug precipitation kinetics.
- At a fixed level of 5% (w/w) in the S-SEDDS formula, the effectiveness of the PPI as evidenced by the particle size counting with FBRM is ranked below: HPMC (E series) > HPMC (K series) > PVP (no effect). Furthermore, the higher viscosity grade of HPMC appears more effective in both E and K series when the other formulation variables are fixed.
- Preliminary PK study in Cynomolgus monkeys showed that AMG517 S-SEDDS formulation exhibits a rapid absorption that is attributed to the supersaturated state generated in vivo.
- When the cellulosic polymer (e.g., HPMC, HPMCAS) was used as a precipitation inhibitor, the precipitates obtained from the in vitro tests were found completely amorphous AMG 517.
- Cellulosic polymers are hypothesized to presumably interfere with the nucleation process of AMG 517 by adsorbing to the surface of the primary nuclei of the drugs, resulting in amorphous drug aggregates.

Chapter 8

Structured Development Approach for Amorphous Systems

Navnit Shah, Harpreet Sandhu, Duk Soon Choi, Oskar Kalb,
Susanne Page, and Nicole Wyttenbach

Abstract A structured development approach is presented to guide the development of stable and commercially viable amorphous formulations. The proposed approach should not only enable the delivery of poorly soluble drugs but also help reduce the API needs, reduce in vivo screening, minimize risks for late-stage development, and ensure consistent quality. During initial assessment, a guided evaluation of the physicochemical properties of the API helps to assess the degree of difficulty for the development. A range of tests including in silico evaluation, high-throughput screening assays, and miniaturized screening tools provide a road map for selecting the appropriate polymer, drug loading, and suitable manufacturing process. A dedicated section provides a review of the characterization tools to assess and quantify the crystallinity, understanding the phase behavior of amorphous solid dispersion, and designing the in vitro dissolution methods. Finally, a reference chart is provided that summarizes the key concepts proposed as part of the structured development approach that can serve as a blueprint for the development of amorphous formulations.

8.1 Introduction

It is well known that utilizing the amorphous form of a drug can be a useful approach to improve the dissolution behavior and bioavailability of poorly water-soluble active pharmaceutical ingredients (Chiou and Riegelmann 1970; Hancock and Parks 2000; Six et al. 2004). However, amorphous compounds are thermodynamically unstable and may crystallize over pharmaceutically relevant timescales, negating any solubility advantage. Amorphous compounds can often be stabilized by combining the active ingredient with a carrier polymer to form an amorphous, molecular-level solid dispersion, as described in several comprehensive reviews (Leuner and Dressman 2000; Serajuddin 1999; Van den Mooter et al. 2001; Janssens et al. 2010). The properties of the resultant solid dispersions are influenced by the physicochemical properties of both the active pharmaceutical ingredient and the carrier polymer. Despite the expanded theoretical and practical knowledge of amorphous systems with respect to thermodynamic and kinetic stability and the availability of various modern instrumental techniques to qualitatively and quantitatively characterize the amorphous system, very few amorphous drug products have been introduced into the market place. This could be due to several factors including:

- Insufficient knowledge of the physicochemical properties of drugs and stabilizers (polymers) and their interactions
- Limitation of API availability during the early stages of development
- Lack of available techniques for prediction of amorphous formulation stability
- Availability of representative processing techniques during early-stage development, especially on small scales (or miniaturized) for formulation screening
- Insufficient time available for structured development

Thus, the formulation scientist uses an empirical approach to develop early formulations using some known polymers at some arbitrary drug loading by solvent evaporation methods. Loss of typical powder X-ray diffraction pattern and/or disappearance of the melting endotherm are used to confirm the formation of an amorphous dispersion, which is then characterized for solubility, dissolution, and short-term stability studies, prior to use in animal PK studies. The empirical approaches currently used are somewhat risky in that the formulation scientists do not have a clear understanding of, nor have time to evaluate various critical aspects, such as: selection of a suitable polymer, selection of drug loading for optimum solid state stability, maintenance of supersaturation during the dissolution process, thorough knowledge of processing techniques, and predictive tools for maximizing the long-term stability of amorphous formulations. This approach generally leads to ambiguity and lack of confidence in the formulation, thus resulting in very few successfully marketed products. In fact, some of the marketed products require very stringent storage conditions to maintain long-term stability. The focus of this chapter is to describe a structured approach for the development of amorphous formulations that should help bolster confidence and provide a formulation with the best chance for success.

8.2 Ideal Amorphous Formulation: Structured Development

An ideal amorphous formulation should maintain long-term physical stability with respect to solid-state properties and maintain supersaturation during the time course of the dissolution process relevant to *in vivo* dissolution, generally about 2–4 h. Among various factors, the selection of polymer and drug loading are two key aspects in the development of an ideal amorphous formulation. The inhibitory effects of polymers against crystallization in the solid state have been attributed to various mechanisms including anti-plasticization by the polymers (Van den Mooter et al. 2001; Oksanen and Zografi 1990), interactions between the API and polymers in solid dispersions (Aso et al. 2002; Taylor and Zografi 1997; Miyazaki et al. 2004), a reduction in local molecular mobility due to coupling between the polymer and API motions (Aso and Yoshioka 2006), and an increase in the activation energy for nucleation (Marsac et al. 2008). On the other hand, maintaining supersaturation during the dissolution process has been attributed to the inhibition of API crystallization from the supersaturated solution by the polymer (Gupta et al. 2004; Tanno et al. 2004) and increased equilibrium solubility of the API due to complexation with the polymer (Usui et al. 1997; Acartürk et al. 1992; Loftsson et al. 1996). Therefore, the ideal formulation should provide solid-state stability and maintenance of supersaturation during dissolution not only initially but also throughout the product's shelf life.

The following steps are described in the chapter as part of the structured development approach to support and strengthen amorphous formulations:

- Comprehensive assessment of physicochemical properties of drug substance, e.g., melting point, heat of fusion, type and number of hydrogen-bonding donor accepting groups, partition coefficient and solubility, solubility parameters, and interaction parameters
- Assessment of physicochemical properties (solubility parameters and solubility) and thermal and mechanical properties of carrier polymers
- Feasibility of drug–polymer interactions
- Assessment of drug solubility and miscibility in polymers
- Miniaturization techniques for the screening of polymers for amorphous drug stabilization (SPADS)
- Selection of processing technology based on the basic knowledge of process and properties of the resulting material linking to downstream processing requirements
- A tool box of various analytical methods to characterize the product in the solid state, during dissolution, and throughout its shelf-life

We believe that using a structured approach to amorphous formulation development consisting of an evaluation of drug substance properties, the selection of a suitable polymer and concentration, and the use of a proper process will enable the development of amorphous formulations with optimum solid-state stability and dissolution performance. An overview of the different stages of the structured approach including the scope, the measurements, and expected outcome is shown in Table 8.1.

Table 8.1 Overview of the structured development approach

| Stage | Scope | Drug substance properties | Polymer properties | Outcome |
|---|---|--|--|---|
| Initial assessment | Pre-selection of polymers based on stability aspects | Solubility parameter pKa value Hydrogen bond acceptor/ donator Melting point | Solubility parameter Ionic nature Hydrogen bond acceptor/ donator Hygroscopicity Glass transition temperature Adequate safety package | Define a range of polymers to be tested in stage 2 (miniaturized assay's) |
| | Pre-selection of manufacturing technologies | Melting point Thermal stability Solubility in organic solvents Stability and solubility at different pH | Processability (thermal stability, melt viscosity, glass transition) | Potentially, exclude a process technology based on drug substance properties – narrow down the range of polymer to be tested in stage 2 |
| Miniaturized assay | Selection of polymers and API to polymer ratio based on dissolution and stability aspects | <ul style="list-style-type: none"> Miniaturized assays to determine the supersaturation potential and amorphous drug stabilization such as the SPADS assay; SPADS “dissolution” SPADS “interaction” SPADS “imaging” | | Final selection of polymer and polymer to API ratio (3–5 formulations) |
| Manufacturing in small scale | Evaluate pre-selected formulations and process technologies | | Assess processability of the selected prototype formulations using different technologies, if feasible | Prototype formulations for first analytical assessment |
| Characterization, stability and dissolution | XRPD, DSC, FTIR accelerated stability, discriminating dissolution | | Re-confirmation of polymer, drug loading and process impact on stability and dissolution | Selection of most viable formulation |

8.3 Initial Assessment

The aim of the initial assessment is to select the most promising polymer(s) for amorphous drug stabilization based on the structure of the compound. This list of polymers can sometimes be further narrowed by excluding manufacturing technologies which cannot be pursued due to specific properties of the drug substance. The data used during this assessment either are based on the structure or are usually measured during early phases of drug development (preformulation). The key steps considered during initial assessment include:

- Collection of drug substance properties
- Assessment of polymer properties (internal database or previous experience)
- Preselection of polymer based on solubility parameter, glass transition temperature, and potential for specific interactions

8.3.1 Collection of Drug Substance Properties

Knowledge of the basic drug substance properties is of utmost importance for the selection of appropriate polymers to stabilize the amorphous form in the solid state as well as during dissolution. As all the necessary data for this evaluation are usually determined in the early phases of drug development (preformulation), there is no additional effort expected. In addition, the clinical dose and the recrystallization tendency of the drug substance might also be considered to assess the feasibility of developing a stable amorphous system. The preselection criteria one could use in order to identify suitable polymers are listed below:

- Melting point and heat of fusion of the crystalline form and the glass transition temperature of the amorphous form (if it can be determined)
- Thermal stability of the crystalline and amorphous form
- Solubility in organic solvents (low or high boiling point)
- Stability and solubility over the pH range (1–10)
- Ionization constants and partition coefficient (as an indicator of hydrophobic interaction vs. electrostatic interaction)
- Hydrogen-bond donor/acceptors
- Calculated solubility parameters

Several key characteristics have been identified for different systems, such as hydrogen-bond donor/acceptor groups, ionic groups, partition coefficient, hygroscopicity, and ratio of T_m/T_g . Friesen et al. (2008) systematically showed the ability to form amorphous systems for a large variety of drug substances based on the T_m/T_g ratio and partition coefficients. While the use of preformulation data to facilitate the selection of polymers is provided in the subsection titled preselection of polymer, a brief synopsis is provided in Sect. 8.5 with regard to their relevance in the selection of a processing technology.

8.3.2 *Collection of Polymer Properties*

Physical stability of the high-energy amorphous form is of vital importance to achieve the desired improvement in dissolution, solubility, and bioavailability. For all practical purposes, this stability is afforded by the polymer, thus making the selection of the polymer and its concentration in the formulations as one of the most critical decisions in the development of amorphous formulations. The key considerations in the selection of polymer generally include:

- Glass transition temperature and molecular weight
- Solubility and/or miscibility of the drug in the polymer
- Hydrophilic/hydrophobic properties
- Hydrogen-bond acceptors/donors
- Ionic nature of the polymer and pH-solubility profile
- Processability (solubility in organic solvents, T_g , melt viscosity, and thermal stability)
- Adequate safety package to support the usage level in the product
- Hygroscopicity
- Degree of supersaturation achieved during dissolution

Other properties, such as: composition of polymer, polydispersity, and monomer levels, are also essential and should be evaluated during development mainly as part of critical material attributes during the Quality by Design phase (QbD) to ensure consistent processing and performance. A list of commonly used pharmaceutical polymers is compiled in Table 8.3, along with some relevant properties. As one can imagine, the list of pharmaceutically acceptable polymers for amorphous formulations is somewhat limited. Although new polymers are being added continuously to the list, a mechanistic understanding of polymer properties needed to stabilize the amorphous system remains somewhat elusive. Some of the key factors related to polymer selection in the design of stable amorphous formulations are discussed in the following sections.

8.3.3 *Preselection of Suitable Polymers*

The phase behavior of polymer-stabilized amorphous formulations depends on the specific interactions between the polymer and the drug. The drug solubility determines the upper limit of the drug concentration that can be safely stabilized by the polymer. Any drug amount higher than that solubility will exist in the metastable state and is prone to revert to a low-energy crystalline state under normal stresses of temperature, pressure, and humidity. Furthermore, these systems may not provide consistent dissolution (or in vivo performance) due to the chaotic nature of the reversion process. A key to the selection of polymer and optimal drug loading is to maximize the interactions between the drug and the polymer. As shown in subsequent sections, specific interactions between the drug and polymer are the strongest, and if favorable, have the best probability of achieving the desired stability.

Although significant efforts have been made to understand and determine drug solubility (crystalline drug) and miscibility (amorphous) in polymers, it still remains a challenge to estimate these values due to low diffusivity and high-molecular weight even at high temperatures, or the relaxation of the amorphous system at lower temperature (Qian et al. 2007; Marsac et al. 2008; Huang et al. 2008). Commonly used methods for estimating the solubility of drugs in polymers include solubility parameter calculations, molecular modeling, molecular dynamic simulation (Gupta et al. 2011), and Flory-Huggins interaction parameter (using thermal analysis and solubility). Additional tools are frequently employed to assess interactions, such as spectroscopic and microscopic, which are discussed in Sect. 8.6 as part of characterization. Some key approaches used for the preselection of polymers are discussed below.

8.3.3.1 Solubility Parameters

The evolution of solubility parameters to predict the solubility of organic compounds originated from the Hildebrand solution theory in 1936, and the symbol delta (δ) was adopted in 1950 to represent the term solubility parameter. The solubility parameter, or cohesive energy density (CED) of a material, is the energy which holds that substance together. It is the amount of energy required to separate the constituent atoms or molecules of the material to an infinite distance, and hence it is a direct measure of the attraction that its atoms or molecules have for one another. Cohesive energy is the net effect of all the interatomic/intermolecular interactions including Van der Waals interactions, covalent bonds, ionic bonds, hydrogen bonds, and electrostatic interactions, induced by dipole and permanent dipole interactions (Hancock et al. 1997). Three main components of the solubility parameters include dispersion, polar, and hydrogen-bonding forces and are frequently calculated using group contribution methods and are used to predict the miscibility of drugs with polymers. Attempts were made to correlate the solubility parameter and miscibility between ibuprofen and several excipients (Greenhalgh et al. 1999). Miscibility was observed when the drug substance and the polymer had a difference in the solubility parameter of less than $7 \text{ MPa}^{0.5}$, and immiscibility occurred when the difference in the solubility parameter is above $10 \text{ MPa}^{0.5}$. It has also been proposed that hydrogen bonding has a stronger effect on solubility compared to dispersion and polar components. The Bagley plot using the three-dimensional solubility parameters seems to be the most efficient way of predicting miscibility. Albers showed that, from the data set investigated, it could be deduced with few exceptions that two substances are miscible if their distance in the Bagley plot is $\leq 5.60 \text{ MPa}^{1/2}$, or if the difference in their total solubility parameters is $\leq 5.4 \text{ MPa}^{1/2}$ (Albers 2008). An example of the Bagley plot is shown in Fig. 8.1. Overall, it should be mentioned that there is no clear cut-off value for the difference in solubility parameters below which systems are completely miscible in all proportions. However, there exists a significant body of evidence suggesting that the ranges suggested by Greenhalgh could provide good guidance. Furthermore, the absolute difference between solubility parameters of

Fig. 8.1 Bagley plot comparing the solubility parameters of several polymers and felodipine, nifedipine, and itraconazol

a drug and polymer should not be considered as an exclusion criterion because other aspects, such as formation of ionic interactions, may help overcome the solubility limitations.

With increasing computational power, molecular dynamic (MD) simulations can be used to calculate the solubility parameter as shown (Gupta et al. 2011). The authors see a clear advantage of these MD simulations as the solubility parameter can be calculated as a function of temperature, and additional functional groups as well as secondary interactions that are not covered in the group contribution methods can also be calculated.

8.3.3.2 Glass Transition Temperature

Amorphous solids are frequently characterized by glass transition temperature (T_g) that corresponds to the temperature at which an amorphous material undergoes a transition from a “glassy state” to a “rubbery state.” Unlike a melting endotherm, this transition is a second order transition and is associated with continuous changes (as opposed to abrupt changes) in thermodynamic properties, such as heat capacity, viscosity, entropy, and volume (see Fig. 8.2). Due to the nature of the transition, its measurement is sensitive to many factors including sample history, rate of cooling, and the presence of impurities.

Despite the difficulty in accurately measuring T_g , it is one of the most commonly used tools to characterize amorphous solids and assess the interactions of different materials, particularly miscibility. Its popularity is associated with the fact that it

Fig. 8.2 Pictorial representation of thermodynamic changes depicting the thermal transitions

represents changes in the kinetic and thermodynamic properties of amorphous materials and is relatively easy to measure using a small amount of sample. As a general guiding principle, amorphous systems with high T_g s are preferred to improve stability as they can exist in a glassy state at room temperature, which has substantially high viscosity ($>10^{13}$ P) limiting the configurational changes and rendering the system immobile. A low- T_g system can be considered only if there are significant interactions between the materials (Chokshi et al. 2008).

If a binary system shows a single T_g , it is expected to be miscible, whereas, two T_g s, or the appearance of a melting endotherm for the drug, would generally indicate immiscibility. Based on free volume theory, the T_g of a mixture as a function of polymer concentration is generally expressed as a weighted average of the T_g s of the pure components and is described by the Gordon–Taylor equation (Gordon and Taylor 1952).

$$T_g = \frac{w_1 T_{g1} + k w_2 T_{g2}}{w_1 + k w_2}$$

In this equation, T_g is the T_g of the blend, T_{g1} and T_{g2} are the T_g s of the pure components, w_1 and w_2 are the weight fractions of each component in the blend, and k is a constant calculated using true density (ρ) and the difference between expansion coefficients of the melt and the glass ($\Delta\alpha$) ($k = \rho_1 \Delta\alpha_1 / \rho_2 \Delta\alpha_2$). For early assessments, k is generally considered a constant. A simplified version of this equation for an ideal system, when $k = 1$, is known as the Fox equation.

As an initial assessment and rough rule of thumb, polymers with high T_g s are preferred especially those that can provide amorphous solid dispersions with a single composite T_g of 75°C or higher (i.e., 50°C above the storage temperature).

8.3.3.3 Specific Interactions

It is well recognized that interactions between a drug and polymer have significant effect on the stability of a high-energy amorphous system. As discussed in the previous section, the interactions between a drug and a polymer can result from several

Table 8.2 Typical bond energy and relative strength of different intermolecular forces

| Type of Interactions | Bond energy (kJ/mol) | Approximate relative strength |
|----------------------------|----------------------|-------------------------------|
| Ionic interactions | 850–1,700 | 1,000 |
| Hydrogen bonding | 50–170 | 100 |
| Dipole–dipole interactions | 2–8 | 10 |
| vanderwaals interactions | ~1 | 1 |

Adapted from Yang and Han (2008)

types of intermolecular interactions, e.g., hydrophobic interactions (due to dispersions forces), hydrogen bonding, or electrostatic (polar or induced-dipole) interactions. As shown in Table 8.2, electrostatic interactions, being strong forces, can provide stability to amorphous solid dispersions.

An understanding of the interactions and their effect on the solubility of a drug in a polymer and the resultant phase diagram determine the space within which high-energy systems can provide maximal benefit. A theoretical basis for the calculation of thermodynamic solubility and kinetic miscibility has been discussed by several researchers (Zhao et al. 2011; Janssens et al. 2010; Paudel et al. 2010).

The Flory–Huggins solution theory is used to describe the free energy change of mixing. The Gibbs free energy change accompanying mixing at constant temperature and pressure is written as:

$$\Delta G_m = \Delta H_m - T\Delta S_m,$$

where ΔG_m is the free energy of mixing, ΔH_m is the enthalpy of mixing, and ΔS_m is the entropy of mixing at absolute temperature T . For most solid dispersions, entropy is usually positive; however, it is the enthalpic term that is critical to achieve the negative free energy required for a stable system.

Flory–Huggins applied the solution theory to represent the enthalpic and entropic terms for mixing process as shown below:

$$\Delta G_m = n_1\phi_2\chi RT + [n_1 \ln \phi_1 + n_2 \ln \phi_2]R$$

1 - polymer, 2 - drug

where n is the number of moles, ϕ is the volume fraction, R is the gas constant, and χ is the interaction parameter. The index 1 represents the polymer, whereas 2 represents the drug substance.

The value of χ is frequently estimated by Hildebrand solubility parameter as follows:

$$\chi = \frac{v'(\delta_1 - \delta_2)^2}{RT},$$

where v' is the volume of the polymer chain segment and δ_s are the solubility parameters of the drug and polymer, respectively. The estimation of “ χ ” can be further improved using the experimentally determined values of solubility parameters or using thermal analysis (see Sect. 8.4). The estimated or determined value of

Fig. 8.3 Free energy of mixing as function of composition at different interaction parameters

“ χ ” is used to construct the temperature composition phase diagram that provides the miscibility regions. A schematic of free energy of mixing versus composition diagram is shown in Fig. 8.3. Note that the negative “ χ ” value favors mixing. The minimum in the free energy diagram corresponds to maximum stability for the system. This temperature–composition phase diagram can be further transformed using the first derivative and second derivative to generate the binodal and spinodal decomposition curves that are used to indicate regions of stability, instability, and metastability.

As shown in Table 8.3, polymers with ionizable groups present opportunities for the formation of hydrogen bonding and/or ionic interactions. It has been generally recognized that proton transfer and exact stoichiometry may not be a requirement for drug–polymer blends due to large differences in the molecular weight. Nevertheless, the presence of ionizable groups can provide secondary structures that are sterically stabilized in addition to reducing mobility. Krill et al. (2009) investigated the miscibility of polymers and highly crystalline additives. They showed that the likelihood of obtaining a miscible system was the highest in the case where an acid–base ionic interaction is involved in the formation of the amorphous state. In the absence of ionic interactions, systems with similar solubility parameters and partition coefficients showed miscibility. Similar interactions are expected between drugs and polymers. Additionally, (Forster et al. 2001a, b) also showed that ionic interactions and solubility parameters play a role in the formation of the amorphous state.

8.3.3.4 Hygroscopicity and Water Activity

Hygroscopicity of a polymer plays an important role in determining the physical stability of an amorphous product, especially during storage. Adsorption of water

Table 8.3 Relevant properties of common pharmaceutical polymers

| Polymer | T_g (or T_m) (°C) | Mol wt (g/mol) | δ (MPa) ^{0.5} | pH solubility | Hygroscopicity (moisture @ 75%RH/RT) | Comments |

can act in many ways to destabilize amorphous systems, such as by weakening the interactions between the drug and polymer, lowering the solubility or miscibility of the drug in the polymer, and lowering the glass transition temperature of the polymer (plasticization). Although the effect of water on the interactions between the drug and polymer is not easy to assess, several authors have evaluated the effect of water on drug solubility and glass transition temperature. Rumondor et al. (2009b) showed that a small amount of water can significantly lower the solubility of felodipine in PVP. Similarly, in another study, it was shown by differential scanning calorimetry (DSC), atomic force microscopy (AFM), and transmission electron microscopy (TEM) measurements that water can irreversibly disrupt the favorable interactions between a drug and a polymer, thus resulting in phase separation that eventually leads to crystallization (Marsac et al. 2008). A modified Flory–Huggins equation considering a water–drug–polymer ternary system was developed by Rumondor et al. (2009b) to estimate the effect of water on the interaction parameters. It was shown that ingress of water can weaken the interactions between hydrophobic drug and hydrophilic polymer, thus resulting in drug-rich phases that induce crystallization. In a study where different polymers were compared, the authors concluded that use of a hydrophobic polymer, such as hypromellose acetate succinate (HPMC-AS), can be beneficial over more hydrophilic polymers, such as povidone or copovidone, to achieve better stability. A similar finding has been shown by Friesen et al. (2008) where the use of HPMC-AS was shown to provide better supersaturation during dissolution that was related to the formation of aggregated structures by HPMC-AS (Friesen et al. 2008). The aforementioned discussion clearly shows that water can interfere with amorphous systems in many different ways. Therefore, polymers with low water activity are expected to provide the best stability for amorphous systems. On several occasions, we have shown that polymers with ionic groups, such as HPMC-AS or methacrylates (Eudragit L100, Eudragit L100-55, Eudragit E100), can help stabilize amorphous systems by not only providing an opportunity for ionic interactions but also by providing low water activity as they are insoluble in water (Chokshi et al. 2008).

8.3.4 Summary of Initial Assessment

As described in this section, it is very important to know the physicochemical properties of the drug substance with respect to its thermal behavior, hydrogen-bond acceptor and donor groups, molecular weight, hydrophobicity, melting point, glass transition temperature, solubility parameter, hygroscopicity, $\log P$, and T_m/T_g ratio. The basic preformulation data can help assess the degree of difficulty a molecule may present in being converted to and maintained in an amorphous form (Friesen et al. 2008). To best match the properties of a drug substance, it is also important to know the physicochemical properties of polymers such as their thermal behavior, hydrogen-bond acceptor and donor groups, molecular weight, hydrophobicity, melting point/glass transition temperature, solubility parameter, and hygroscopicity.

A comprehensive summary of polymer properties is provided in Table 8.3. The initial selection of polymers should be based on solubility parameters, functional groups, and thermal behavior including melting point and T_g . Thermal stability and solubility in organic solvents are critical for the selection of the processing method (further discussed in Sect. 8.5). The initial screening will help to narrow down the list of polymers, e.g., considering similar solubility parameters or the possibility of ionic interactions between a weakly basic drug and enteric polymers.

The next step in the process of structured development is the determination of appropriate drug loading. Calculations of Flory–Huggins interaction parameters based on either solubility parameters or melting point depression methods are frequently used to estimate the drug loading. Ideally, the drug loading would be close to its solubility in the polymer at room temperature, and under no circumstances should the drug load in a solid dispersion be above its solubility at T_g . After a review of the preformulation properties and initial assessment, small-scale experiments are conducted to further narrow down the choice of polymer and drug loading that has the potential to provide the best stability and supersaturation.

8.4 Miniaturized/Small-Scale Experiments: Selection of Polymer and Drug Load

After a careful evaluation of drug and polymer properties and *in silico* assessment, one can narrow down to potential polymers and drug loads in the amorphous solid solution. The next phase in the development of amorphous dispersions is the evaluation of different compositions by miniaturized or small-scale experiments to narrow down the choice of polymer and to get an assessment of drug loading. In the past, these systems were prepared by different small-scale low-throughput methods, including: rotary evaporator (Moneghini et al. 1998), spray-drying (Corrigan et al. 1985), freeze drying (Engers et al. 2010), amorphous film preparation by the ultra-rapid freezing technique (Overhoff et al. 2007; DiNunzio et al. 2008), or small-scale ball milling experiments (Patterson et al. 2007), hot-plate mixing (Chokshi et al. 2005), hot-melt extrusion (Miller et al. 2008), or beaker melt method (Forster et al. 2001a, b). However, a new trend has recently emerged where miniaturized experimental screening systems are being utilized for the evaluation of suitable polymers and additives (or mixtures thereof) for amorphous formulations. These systems use typically less than 10 mg of compound per test sample and work in the 96-well format. The use of these miniaturized systems has the potential to facilitate amorphous formulation development by saving valuable time and resources (manpower and compound). Ideally, the miniaturized assays are partly or fully automated by an assembly of different modules, for instance: robotic systems, high-throughput analytical systems, and specific software and database tools, allowing dozens or hundreds of screening experiments in a short period of time. As discussed before, the development of suitable amorphous systems requires miniaturization of the

preparation methods and characterization tools including the analytical methods to assess the supersaturation potential. The discussion in the following section is focused on these aspects.

8.4.1 Assessment of Supersaturation, Miscibility, and Stability

The concept of generating and maintaining supersaturation has been described as the “spring and parachute approach” by Guzmán et al. (2007). In the case of a molecular dispersion (solid solution), release of drug molecules is dictated by dissolution of the hydrophilic carrier (spring function) and leads to a supersaturated state of the drug in solution. Two different miniaturized methods have been applied to assess the supersaturation potential of excipients with poorly water-soluble drugs: co-solvent quenching and amorphous film dissolution. Examples for both methods described in the literature are shown in Table 8.4.

The co-solvent quench method is currently the most common method used for initial polymer screening. In this method, drug is dissolved in a water-miscible solvent with high drug solubility. A small aliquot of the solution is then dispersed in the aqueous phase to create a supersaturated system. In order to determine the extent of drug precipitation, the concentration of the dissolved drug within the aqueous phase or the mass of drug precipitated can be assayed or measured indirectly by turbidity measurement. Alternatively, the film dissolution method involves parallel dissolution screening of solid dispersions with different compositions and drug loads prepared by solvent casting. Amorphous drug films are prepared from mixtures of drug and excipient(s) dissolved in a volatile organic solvent. The organic solvent is then evaporated resulting in a thin film of the formulation. The dissolution medium is added to the well and the drug concentration is determined as a function of time.

With respect to the stability, drug–polymer miscibility is essential for the stability of amorphous pharmaceutical compositions because immiscibility can result in the formation of drug-rich domains that may be prone to recrystallization. Other important factors strongly affecting the stability of amorphous systems include solid-state solubility and drug–polymer interactions. The miscibility or homogeneity of these pharmaceutical systems can be evaluated experimentally by different analytical techniques.

Qualitatively, the miscibility of drug and polymer can be assessed by simple DSC measurements, in which mixtures of drug and polymer are mixed and heated in a DSC pan to observe the change of glass transition temperatures. Generally, miscibility of drug and polymer are assessed on the second scan after the system has been heated beyond the melting point of the drug. If the drug is thermally labile, amorphous drug and polymer can be casted in a DSC pan followed by evaporation of the solvent. A general rule of thumb is that a single T_g suggests miscibility, observation of the two T_g s corresponding to individual components suggests complete immiscibility, and two T_g s in between the two individual T_g s suggests partial miscibility.

^aSPADS approach

This DSC technique is simple and rapid in obtaining essential information on miscibility but is very crude in that quantitative miscibility information is lacking and the miscibility is given only near the glass transition temperature. In addition, if the drug and polymer have similar T_g s, or the change in heat capacity around the T_g is small, then this method does not provide much insight into the miscibility of the drug and the polymer.

More detailed and quantitative miscibility values can be derived by studying drug melting point depression by the polymer using DSC (Zhao et al. 2011).

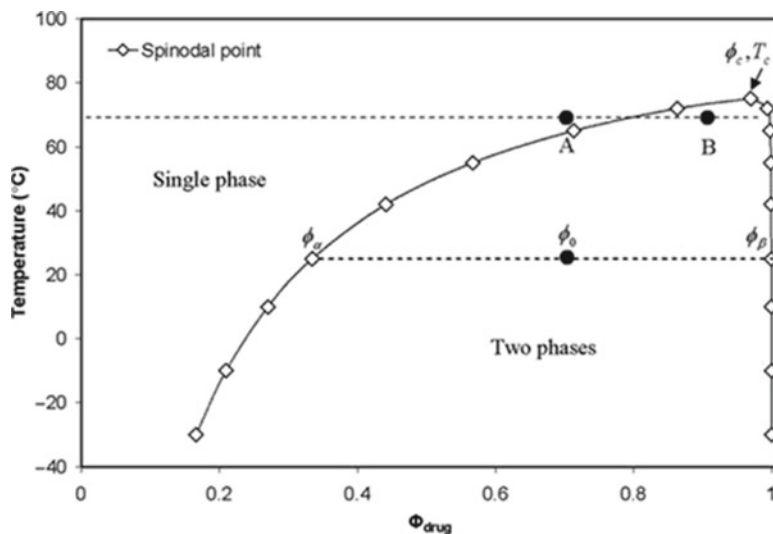

Fig. 8.4 Temperature–composition phase diagram of indomethacin in PVPVA 64 polymer matrix

The Flory–Huggins interaction parameter, χ , can be calculated from the melting point depression data which are then used to construct the temperature–composition phase diagram. The solubility and miscibility of a drug and polymer at any temperature can be extracted once the temperature–composition diagram is available. Figure 8.4 shows an example of a temperature–composition phase diagram of indomethacin in a PVP VA 64 polymer matrix. At ambient temperature, indomethacin is predicted to be miscible up to 30 wt% in PVP VA64.

8.4.2 Miniaturized Methods and the SPADS Approach (Screening of Polymers for Amorphous Drug Stabilization)

Miniaturized methods used to experimentally evaluate the homogeneity and stability of a glass solution are primarily based on amorphous film samples that are analyzed for recrystallization or phase separation by different analytical techniques, e.g., by polarized light microscopy, DSC, XRPD, FT-IR spectroscopy, Raman spectroscopy, or atomic force microscopy (AFM). Amorphous films are usually prepared by evaporation of organic drug–excipient solutions on different carrier systems, such as glass slides, cover slips, 96-well microplates, or aluminum pans. The stability of the amorphous systems is assessed by reanalysis of the samples after storage at accelerated conditions (temperature and humidity). Different miniaturized methods to evaluate amorphous drug stability are presented in Table 8.5.

Fig. 8.5 Example of a 96-well plate-filling scheme used in the SPADS dissolution assay

The SPADS approach has been developed at Roche for solid dispersion screening. It combines the assessment of supersaturation potential, the evaluation of drug–polymer miscibility, and the stability of amorphous systems. The aim is to rapidly identify prototype amorphous compositions suitable for preclinical studies and early-stage clinical trials.

The SPADS approach consists of three different miniaturized assays (1) SPADS dissolution, (2) SPADS imaging, and (3) SPADS interaction assay. It is a two-step approach; only the combinations showing promising dissolution behavior are further characterized with respect to their solid-state properties (SPADS imaging and interaction assays). The three SPADS assays will be described in more detail in the following subsections.

8.4.2.1 SPADS Dissolution Assay

The SPADS dissolution assay is performed on amorphous drug–polymer films prepared in 96-well plates by solvent-based film casting. Specific drug–polymer pre-mixtures are prepared from excipient and drug stock solutions in volatile solvents (e.g., acetone, ethanol, and methanol). The pre-mixtures are distributed into a 96-well plate according to a predetermined filling scheme and the amorphous films are generated by solvent evaporation. To illustrate the method, an example of a possible filling scheme is given in Fig. 8.5. In this example, binary drug–polymer systems with seven polymers at different drug–excipient ratios are tested.

The dissolution screening is performed by adding a stirring bar and a 200 μL dissolution medium (e.g., FaSSIF, pH 6.5) to each well of the 96-well plate. The microtiter plate is closed and mixed by head-over-head rotation at 37°C. One 96-well plate is prepared per time point. Generally, two time points, 60 min and 180 min, are considered adequate to describe the dissolution profile. After mixing the plate for the desired time, 100 μL of the solution are collected and transferred to a 96-well filter plate. Filtration is performed by centrifugation. The filtrates are collected in a new 96-well plate. Drug content in the filtrates is determined by UPLC after appropriate dilution. Figure 8.6 shows the results of an SPADS dissolution screening experiment with a poorly soluble Roche development compound using the filling scheme presented in Fig. 8.5. In this example, the most promising polymer from the supersaturation perspective appeared to be Eudragit E PO, since highly supersaturated solutions of the drug were observed at all drug loads for at least 3 h.

8.4.2.2 SPADS Imaging Assay

Optical microscopy and AFM are applied to analyze the molecular homogeneity and stability of promising amorphous API–polymer combinations on micrometer and nanometer scales using the method developed by Lauer et al. (2011). For AFM investigations, glassy film fracture surfaces on glass slides are generated to discriminate between homogeneously and heterogeneously mixed drug–polymer combinations. The homogeneous combinations are further analyzed for physical stability after exposure of the samples to stress conditions (accelerated temperature and humidity, e.g., at 40°C/75% RH) for some hours.

8.4.2.3 SPADS Interaction Assay

The SPADS interaction assay is used to study molecular interactions between drug and polymer. Amorphous films are prepared in commercially available 100- μL aluminum pans (used for DSC measurements) by solvent casting. The procedure of film preparation is identical to the procedure used in the SPADS dissolution assay with the only difference that the films are prepared in aluminum pans distributed into a 96-well plate. FTIR spectra are measured in reflection mode using a standard FTIR microscope. FTIR spectroscopy is sensitive to changes in the hydrogen-bonding network and protonation status of the drug, polymer, and water present in the system. FTIR spectra of the solid dispersions are compared with the spectra of both the pure amorphous drug (rather than the crystalline forms) and the pure polymers. Hydrogen-bonding significantly influences peak shapes and intensities, generally resulting in peak broadening and peak shifts.

Fig. 8.6 Results of a SPADS dissolution experiment in Fassif pH 6.5 with a poorly soluble Roche development compound. For details, see text

Table 8.6 Example of a summary table used for the rational selection of suitable prototype solid dispersion compositions and drug loads for further processing

| System | Supersaturation potential | Solid state miscibility/solubility/stability | Possible drug load (%) (w/w) | System selected for further processing |
|---|---------------------------|--|------------------------------|--|
| PVP VA64 | - | - | 10 | No |
| Eudragit E PO | ++ | - | 10 | No |
| Eudragit L100-55 | + | ++ | 10–50 | Yes |

Rating categories are: poor (-), acceptable (+), excellent (++)

8.4.3 Summary of the Small-Scale Experiments: Selection of Polymer and Drug Load

All analytical results obtained from initial assessment, miniaturized or small-scale experiments, are collected, assessed, and tabulated for comparison. The collected data are used to preselect the most promising prototype amorphous compositions and drug loads that will be subjected to small-scale solid dispersion preparation in a manner relevant to the intended final dosage form. These scaled-down processes include mini-extrusion for hot-melt extrusion, mini-fluid bed systems for coated bead systems, or mini-spray dryers if spray drying will be an option. Based on our experience, this step is very important since various amorphous solid dispersions often have different stability and biopharmaceutical properties based on how they were generated, even when containing the same composition and drug load. An example of a summary table used for the rational selection of suitable prototype solid dispersion compositions and drug loads for further processing is presented in Table 8.6.

8.5 Selection of Most Suitable Technology

After having selected some promising polymers and drug loads, selecting the right processing technology is essential. The selection of the most appropriate process for the manufacture of a solid dispersion depends on the physicochemical properties of the API and the polymer (solubility, melting point, and T_g), the properties of the solid dispersion in terms of further downstream processing (e.g., particle size, and bulk density), and the finished drug product properties (e.g., stability and dissolution). Additional criteria that should be taken into consideration are the availability of the equipment, the robustness of the manufacturing process, and the intellectual property considerations.

A physically stable solid dispersion of an amorphous API in a polymer can be achieved if the drug and the polymer are intimately mixed at the molecular-level, i.e., a solid solution. Molecular-level mixing is achieved either by dissolution of both components in a solvent followed by solvent removal or by directly mixing both components as liquids as is accomplished by melting methods (Chiou and Riegelman 1971). The most relevant technologies for the manufacture of solid dispersions in the pharmaceutical industry are (1) spray-drying, (2) melt extrusion, (3) and co-precipitation. The following section discusses these technologies including a brief overview, schematic of the physical processes, and a summary table with the associated advantages and disadvantages (Table 8.7). A general screening approach is presented in Sect. 8.5.2 to help select the appropriate technology. Although several other technologies can be used to produce amorphous solid dispersions such as: spray granulation, fluid bed layering, co-grinding, ultra-rapid freezing, and supercritical fluid processing; they have limited applications either due to slow evaporation rate, solvent solubility, and/or incomplete conversion.

8.5.1 Overview of Key Manufacturing Technologies

8.5.1.1 Spray-Drying

Spray-drying is well established as an industrial process for transforming solutions, emulsions, or suspensions into a dry powdered form. This is accomplished by pumping a feed solution (e.g., drug and polymer dissolved in a volatile solvent) into an atomizer inside the drying chamber. The atomizer breaks the solution into a plume of small droplets (normally less than 100 μm in diameter). In the drying chamber, the droplets are mixed with a hot drying-gas stream (air or nitrogen). The heat is transferred from the hot drying gas to the droplets to provide the latent heat of vaporization required for rapid evaporation of the solvent from the droplets. By controlling the inlet and outlet temperatures of the spray dryer, together with the spray rate and air volume that are introduced to the spray dryer, the morphology, particle size, and density of the resulting solid dispersion powder can be controlled. The solid powder is typically collected from the gas stream using a cyclone or a filter. The spray-drying process can be performed over a wide range of scales (from milligrams/grams to tons of drugs) (Friesen et al. 2008). Nevertheless, spray-dried material is often very fine and contains a high amount of residual solvents. This may have a negative effect on the downstream process (flow and density of particles) and the stability of the spray-dried solid dispersions (recrystallization of the amorphous drug). In order to improve the properties of the spray-dried material, spray-dryer layouts with an additional external fluid bed or an internal fluid bed are available to improve the drying efficiency and to agglomerate the fines (Masters 1991). A thorough discussion of spray-drying technology and its application to the formulation of poorly water-soluble drugs is provided in Chap. 10.

Table 8.7 Pros and cons of different processing technologies

| Process | Pros | Cons |
|-----------------|---|---|
| Spray drying | <ul style="list-style-type: none"> – Rapid removal of solvent and fast solidification – Equipment available from lab to full-scale commercial production – Relatively low temperature processing feasible for highly volatile solvents (reducing thermal stress and degradation of the API) – Continuous processing | <ul style="list-style-type: none"> – Use of organic solvents (environmental safety) – Difficulty to identify a common volatile solvent for API and polymer – Difficulty to remove solvent completely requiring secondary drying process – High manufacturing cost – Generally results in very fine particles with low bulk density and poor flow properties |
| Melt extrusion | <ul style="list-style-type: none"> – Short exposure to processing temperature (residence time less than a minute) – Non-solvent processing (eliminate the need for solution preparation and removal steps) – Customizable process (screw/die design, temperature profile, and solvent addition) – Effect of humidity and oxygen can be almost completely eliminated – Robust process control and easy scale-up – Continuous process – Broad selection of excipients with different molecular weight and physico-chemical properties | <ul style="list-style-type: none"> – High energy mainly related to shear forces and temperature (high thermal stress in case of high melting compounds) – High melt viscosity causing torque limitations – High density and low porosity of the thermoplastic extrudates reduces the compaction of the material |
| Coprecipitation | <ul style="list-style-type: none"> – Suitable for compounds that cannot be processed by spray drying (due to low-solubility in volatile organic solvents) or melt extrusion (due to high melting point with thermal degradation) – Provides high degree of supersaturation due to use of ionic polymers – High exposure and prolonged plasma profile due to pH-dependent solubility – Amenable for continuous processing | <ul style="list-style-type: none"> – Requires polymers with differentiated solubility in solvent and antisolvent – Weak bases (and acid drugs) exhibit significant solubility in acidic (and basic) solvents – Adequate solubility in water miscible solvents (for ease of extraction); may require multiple washings to remove solvents – Downstream processing to be considered carefully |

8.5.1.2 Hot-Melt Extrusion

Hot-melt extrusion (HME) is frequently used in the pharmaceutical industry for developing solid dispersion formulations. HME is the process of pumping raw materials with a rotating screw(s) under elevated temperatures through a die to form a product of uniform shape. The intense mixing and agitation imposed by the rotating screws results in a uniform dispersion. Generally, the extruder consists of one (single-screw) or two (twin-screw) rotating screws in a stationary barrel. Twin-screw extruders can be operated in co-rotating or counter-rotating modes. Co-rotating twin-screw extruders are widely used since they can be operated at high screw speeds, yielding high output, good mixing, and good conveying characteristics. A fully intermeshing type of screw design is self-wiping, where it minimizes the stationary zone and prevents localized overheating of material in the extruder. The screw is typically modular and is divided into three sections along the lengths of the barrel: feeding, melting or compression, and metering. In the feeding section, the material is transferred from the hopper to the barrel. In the compression zone, the polymer usually starts to melt due to the thermal energy that is generated by shear forces imposed by the rotating screw and from conduction from the barrel via electrical heating bands. The temperature of the melting zone is normally set 10–60°C above the melting point of semi-crystalline polymers or the glass transition temperature of amorphous polymers to ensure consistent flow. The metering zone is designed to reduce pulsating flow of the molten polymer and provide uniform delivery of the material through the die. The screw configuration can be modified by changing the screw elements to optimize the shear, residence time distribution, and/or product characteristics (Crowley et al. 2007). HME requires pharmaceutical grade polymers that can be processed at relatively low temperatures due to the thermal sensitivity of drugs and polymers. For most polymers, temperatures between 120 and 180°C have been used. For a complete discussion of HME technology, the reader is referred to Chap 9 of this text.

8.5.1.3 Co-precipitation

The term co-precipitation has been used in the literature to describe amorphous solid dispersions produced when the drug and the polymer are precipitated together by changing the solubility conditions, either by addition of an anti-solvent or by evaporating the solvent (Simonelli et al. 1969). Further attempts have been made to co-precipitate a solution of drug and polymer in ethanol by addition into aqueous solution; however, the characteristic crystalline and thermal peaks were still present, indicating incomplete conversion to the amorphous form (Kislalioglu et al. 1991).

Based on the principle of solvent-controlled precipitation, a novel technology referred to as microprecipitated bulk powder (MBP) has been developed that provides complete conversion of a drug to the amorphous form, for a large variety of compounds (Albano et al. 2002;(Shah et al. 2008). The MBP technology

is particularly suitable for highly insoluble compounds for which the utilization of spray drying or hot-melt-extrusion technologies is not feasible. With this technology, a solution of drug and stabilizing polymer is introduced into an anti-solvent that precipitates the drug and the polymer(s) simultaneously to form the MBP. Under appropriate processing conditions, the drug is uniformly embedded in an amorphous form in the polymer. The MBP process is particularly suitable for compounds that may have low-solubility in commonly used solvents, such as acetone or ethanol, but have sufficient solubility in solvents, such as dimethylacetamide (DMA), dimethylsulfoxide (DMSO), dimethylformamide, or *N*-methylpyrrolidone (NMP). Based on the ionic nature of the compound and the polymer used in this process, the solvent-controlled precipitation is carried out under either acidic or basic conditions.

8.5.2 Screening of Manufacturing Processes

The key physicochemical properties of the API and polymer that determine the selection of the manufacturing technology are:

- Thermal properties (melting point or T_g)
- Thermal stability
- Stability in solution
- Solubility in water
- Solubility in organic solvents

As discussed in [Sect. 8.3](#), these properties should be assessed to preselect certain API-polymer systems for a specific technology and allow the formulator to rank order different technologies. In a second step, the ranking should be confirmed by manufacturing trials on small-scale equipment. The physicochemical properties relevant to each technology are discussed in this section.

8.5.2.1 Spray Drying

The underlying principle for the manufacture of a solid dispersion by spray drying is to dissolve a physical mixture of the drug and the polymer in a volatile solvent followed by the evaporation of the solvent. In order to produce a molecular dispersion of the drug and the polymer after evaporation of the solvent, both components have to fully dissolve in the solvent or the solvent mixture. Key parameters that are critical for the manufacture of a solid solution by solvent evaporation are selection of a suitable organic solvent, viscosity of the feed solution, and the residual solvents in the solid solution.

A suitable solvent or solvent mixture must meet the following criteria:

- High solubility for the drug and the polymer: To reduce the amount of solvent needed to dissolve the drug/polymer mixture [to gain a high drug loading of the

spray solution (feed solution)], thereby reducing the overall processing times and the environmental burden. For a commercially viable process, solubility of approximately 100 mg/mL and above is preferred; however, the solubility of 50 mg/mL is considered essential.

- Low viscosity of the feed: To improve atomization and facilitate solvent evaporation, thereby minimizing the risk of physical instability (recrystallization of the drug due to the plasticizing effect of residual solvents).
- Low toxicity of the solvents (ICH Q3C Class 2 and 3) for personal and environmental safety.
- Low boiling point to ease evaporation of the solvent: drying can be performed at lower temperature, lower thermal stress, and less thermal degradation of the drug.
- Solvent mixtures: Solvents that can form azeotropes are preferred because non-azeotropic solvent mixtures will have different evaporation rates during drying that may lead to either phase separation or crystallization of the API during evaporation.
- Sufficient stability of the API in the feed solution.

Potential No-Go criteria for a spray-drying manufacturing process are therefore:

- The stability of the API in solution or the thermal stability of the API at the processing temperature (outlet temperature) is not sufficient.
- Only a low drug load of the feed can be achieved that results in long processing times, which may not be acceptable for commercial production.
- A highly viscous feed may not allow for sufficient atomization, leading to insufficient evaporation of the solvent after drying that may impact the stability of the solid solution (plasticizing effect of residual solvents).
- In case the outlet temperature is higher than the T_g of the spray-dried product, material may stick to the walls of the spray drier, resulting in a low yield that is not acceptable for commercial production (Patterson et al. 2007, 2008).

The spray-dried material needs to be free flowing to facilitate further downstream processing, e.g., tableting, and should have a minimal amount of residual solvents (potential risk of recrystallization).

8.5.2.2 Melt Extrusion

The viability of melt extrusion depends on the ability to form a one-phase solid solution. API and polymers are subject to elevated temperatures, high pressure, and intensive mixing during the HME process (Patterson et al. 2008). Depending on the process conditions, the crystalline drug either melts or becomes solubilized in the molten polymer. The latter allows the manufacture of a solid dispersion at temperatures below a drug's melting point. The recrystallization of the drug during the cooling of the extrudate is retarded due to reduced solute migration and the reduction of nucleation kinetics by the viscous polymer medium.

The selection of optimal melt extrusion conditions depends on the chemical stability of the drug and the polymer and the physical properties of the polymer. The key considerations to establish the most appropriate process parameters for HME include (Crowley et al. 2007):

- Melting point/ T_g /processing temperature: Minimum temperatures are required for extrusion. To reduce melt viscosity and thereby facilitating material transfer of the material in the extruder, the processing temperature of a hot-melt extruder should be set approximately 10–20°C above the melting point of a semi-crystalline polymer, or the T_g of an amorphous polymer (Chokshi et al. 2005). On the other hand, if the temperature is too high, thermal stresses during melt extrusion may cause degradation of API and polymer. Therefore, HME requires pharmaceutical-grade polymers that can be processed at relatively low temperatures due to the thermal sensitivity of many drugs.
- Melt viscosity of the polymer: Polymers with low melt viscosities and high thermal conductivity yield a more efficient melting process (Crowley et al. 2007). If the melt viscosity of the polymer is too high, it may limit miscibility of the API and the polymer (Forster et al. 2001a, b).
- Miscibility: In order to form a one-phase mixture, the two molten components have to be miscible. Based on the Gordon–Taylor equation, if the API and the polymer have ideal mixing behavior, the mixture will have a single T_g that ranges between the T_g of the pure components and depends on the relative proportion of each component. The changes in melting point or T_g as a function of polymer concentration provides the phase diagram to establish the boundary of solid state miscibility and helps to select the processing temperature (Chokshi et al. 2005).
- Solubility: Beside the miscibility between drug and carrier, the solubility of the crystalline drug in the polymer is critical for the stability of the extrudate. Crystallization of a miscible API/polymer system can occur if the solubility limit has been exceeded and the conditions are favorable for crystallization (Marsac et al. 2006). The extrudate is thermodynamically stable when the solubility of the drug in the carrier is not exceeded (Breitenbach 2002). Therefore, the drug load of the formulation needs to be adapted accordingly.

The combination of solubility parameters with thermal analysis of drug/excipient miscibility can be used to predict the formation of a glass solution with melt extrusion. Similarly, physico-mechanical characterization of drug and polymer mixtures can provide insights regarding the miscibility of the binary systems and their behavior during melt extrusion with small quantities of drug. T_g analysis by DSC as a function of the polymer concentration provides a baseline for setting the extrusion temperature and helps to assess the miscibility of the system. In addition, rheological properties (zero rate viscosity and activation energy) of the material as a function of shear rate and temperature are key considerations in establishing the HME process. The usual conditions for Go-No-Go criteria are high melting point, thermal instability, and high melt viscosity.

8.5.2.3 Microprecipitated Bulk Powder

In the MBP process, the API and the ionic polymer are dissolved in a suitable solvent that is introduced into an antisolvent that precipitates the drug and the polymer simultaneously. The residual solvent is removed by a series of washing steps followed by filtration and drying. Due to the nature of the process, it is used only when other means of making amorphous dispersion are not feasible. The key considerations for the MBP process are:

- Selection of a suitable solvent and antisolvent: In addition to the requirements for amorphous form stability, the MBP process requires careful evaluation of API and polymer solubility in solvents and antisolvents. Since ionic polymers are primarily used for this process, the pH of the precipitating medium is also critical. Furthermore, the residual solvent in the product can also be critical.
- Solvent–Antisolvent ratio: To enable rapid quenching of the amorphous form, the solvent/antisolvent ratio needs to be optimized. Generally, a ratio of 1:5–1:10 is required to achieve rapid precipitation rate.
- Processing conditions: The mode of solution addition to antisolvent, feed rate, hydrodynamic conditions, and precipitation temperature merit careful evaluation.
- Isolation of the precipitated material: The material can be converted to powder form by several means ranging from spray drying and lyophilization, to filtration and conventional drying (fluid bed/forced air oven). The drying of aqueous material needs careful evaluation of the temperature/time profile as the wet amorphous material in the aqueous phase could be more susceptible to reversion.

8.5.3 Downstream Processing and Final Product Properties

Finally, the properties of the solid dispersion in terms of further downstream processing (e.g., particle size and bulk density) and the finished drug product properties (e.g., stability and dissolution) have to be considered when selecting the most appropriate manufacturing process. If the solid dispersion is too fine, the particles tend to have poor flow properties that can impact the content uniformity of the finished product. Furthermore, the content of residual solvents in spray-dried solid dispersions (lowering the T_g of the system) can have a significant impact on the chemical and physical stability of the finished product. For the characterization of the solid dispersion and the finished product, several analytical technologies are available, as described in [Sect. 8.6](#).

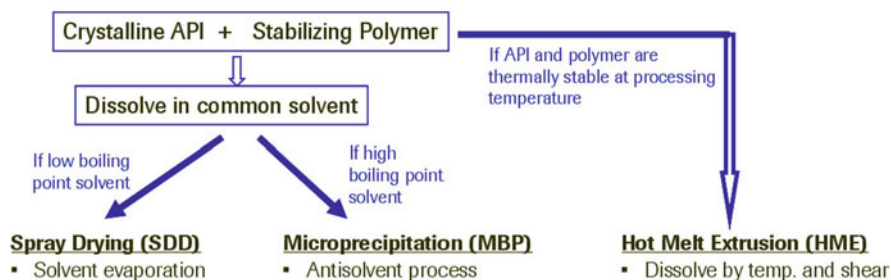

Fig. 8.7 Schematic of key processing technologies for producing amorphous dispersion

8.5.4 Summary of Processing Technology

A schematic of key processing technologies is presented in Fig. 8.7. Overall, the selection of a suitable polymer and the optimal manufacturing process should be based on the following activities:

- Solvent screening (water, organic volatile solvents, and high-boiling solvents)
- Thermal behavior of the API and the polymer (melting point, T_g , and melt viscosity)
- Drug–polymer interaction studies (miscibility and solubility)
- In silico based on solubility parameters
- Thermal methods or other miniaturized methods
- Drug–polymer compatibility testing (to assure chemical and physical stability)
- Thermal stability and stability in solution
- Powder characterization (flow and particle size distribution) of the intermediate (solid dispersion)
- Final drug product characteristics (processing, stability, uniformity, dissolution rate, etc.)

8.6 Characterization of the Amorphous Systems

An amorphous material is generally defined as a solid material that lacks long-range symmetry operators (translational, orientational, and conformational operators), which are characteristics of crystalline material. An amorphous system is considered to be a disordered system with random molecular configuration and packing of individual components, in which individual molecules are randomly oriented to one another and exist in a variety of conformational states. Furthermore, amorphous formulations may possess local and short-range order crystallites, residual crystallinity, and different molecular density regions, as exemplified by alpha and beta relaxations.

Various levels of micro- and macroheterogeneity may be present in amorphous formulations to add complexity. Consequently, gaining insight into amorphous systems to address the formulation challenge is also an analytical challenge and frequently limits development of a stable amorphous formulation.

For successful amorphous formulation development, it is imperative to have suitable analytical techniques to characterize the materials produced and to assess success at each step. The complexity of analytical testing may vary depending on the developmental stage, from simple qualitative testing at an initial stage to comprehensive and quantitative testing at the clinical manufacturing stage. Regardless, for successful amorphous formulation development, it is critical to understand how the amorphous system is being formed, to determine whether or not the crystalline drug is completely converted to an amorphous state, to understand how the drug and the polymer molecules are arranged in an amorphous solid dispersion, and to determine the uniformity of the formulation produced. Knowledge of these attributes will help scientists to not only assess the risks associated with amorphous formulations but also to mitigate those risks by designing optimal formulations (polymer, drug loading, and process). Moreover, this helps the formulation scientists to predict the *in vitro* and *in vivo* performance as well as long-term stability.

In this section, commonly used analytical techniques will be briefly discussed for their merits and limitations in two groups distinguished by the information acquired. First is the set of techniques used to exclude crystallinity in an amorphous system. Obviously, this is the most critical test as the principal impetus of making amorphous systems is to convert a crystalline drug into an amorphous state, and the assurance of complete conversion to amorphous state is of utmost importance. The second set of techniques includes the tests that are used to study the properties of amorphous formulations, i.e., their molecular arrangement and their behaviors. Understanding the molecular arrangement of drug and polymer molecules in amorphous formulations is critical to predict the stability and to understand the *in vitro*/*in vivo* performance. Lastly, trends in amorphous formulation stability predictions are briefly discussed, together with experimental techniques that can be employed. Table 8.8 highlights the differences in physicochemical properties between crystalline and amorphous materials that can be further explored.

8.6.1 *Detection of Crystallinity in Amorphous System*

Many attempts have been made to determine the degree of crystallinity or amorphicity of amorphous formulations. Without doubt, this is the most critical testing in the evaluation of amorphous formulations. Inappropriate selection of polymer, inadequate drug loading (beyond miscibility), and poor process control during pharmaceutical manufacturing will result in incomplete conversion of a crystalline drug to an amorphous state. Any trace level of crystalline drug in amorphous formulations may serve as seeds for recrystallization during *in vitro* and *in vivo* dissolution or during storage, which may jeopardize the entire development program.

Table 8.8 Comparison of physicochemical properties between crystalline and amorphous drug

| Attributes | Crystalline drug | Amorphous drug |
|-----------------------|--|--|
| Thermal behaviors | Exhibits well defined thermal behavior such as melting point and heat of fusion | Exhibits no clear melting phenomenon, but usually exhibits glass transition temperature |
| Birefringence | Except cubic, crystalline material is anisotropic and exhibits birefringence | Amorphous material is isotropic and exhibits no birefringence under cross polarization |
| X-ray diffraction | Crystalline material including liquid crystal and plastic crystal reflects X-ray radiation exhibiting characteristic diffraction pattern | Lacking periodicity, does not reflect X-ray beam and exhibits characteristic amorphous diffused halo |
| Energy level | Comparatively low in energy state, exhibits lower solubility, slower dissolution, and more stable | Comparatively higher in energy state, and exhibits higher solubility, faster dissolution and less stable |
| Mechanical properties | Lower specific molecular volume, leading to denser and harder material | Randomness and irregular packing causes higher molecular volume and less dense material |
| Spectroscopy | Intermolecular interaction to adjacent molecules is well defined, resulting in well characteristic spectrum | Varying configurational states and intermolecular interaction to adjacent molecules results in broad and diffused spectrum |

The following techniques are frequently employed to detect the degree of crystallinity

8.6.1.1 X-Ray Powder Diffraction

X-ray powder diffraction (XRPD) is the most widely used and perhaps the most definitive technique used in detection and quantification of crystallinity. Absence of sharp Bragg's peaks corresponding to the crystalline drug suggests a formulation is in an amorphous state. It is important, however, to note that XRPD detects the presence of molecular order; therefore, the disorder (amorphous state) is only implied by the absence of the order (long-range symmetry order). XRPD is one of the most widely attempted quantification techniques, in which the degree of crystallinity is determined from the intensity of crystalline peaks in the sample. A calibration curve can be prepared by appropriately mixing pure crystalline and pure amorphous standards in various ratios in a respective polymer matrix, as shown below. Although challenges and debate exist regarding utilization of this two-state calibration model to determine crystallinity in amorphous formulation where disorder is likely continuous, this is probably the only validated model that can be used. Limit of quantitation is typically in the range of 5% w/w, depending on intensity of the crystalline peaks.

8.6.1.2 IR and Raman Spectroscopy

Vibrational spectroscopy, such as IR and Raman spectroscopy, can be used to detect the variations in vibrational energy between amorphous and crystalline states. In general, sharp vibrational peaks indicate crystallinity, whereas a broad hump suggests amorphicity, as a result of disorder in molecular arrangements. Having a single crystal structure will aid the interpretation of vibrational spectrum pointing to the region where intermolecular interaction occurs. Using the calibration model described above, IR and Raman spectroscopy can be used to determine the crystallinity of an amorphous formulation.

8.6.1.3 Differential Scanning Calorimetry

DSC is probably the most versatile and widely used technique in the characterization of amorphous formulations including quantification of crystallinity. In DSC, samples are heated at constant rate, while heat flow is continuously being monitored, and the temperatures at which thermal events occur are recorded. Thermal events can be glass transition, (re)crystallization, melting, and decomposition. From thermal events, melting and (re)crystallization energy and changes in heat capacity at glass transition can be measured, which can be used to quantitate the crystallinity or the amorphicity. To quantify crystallinity, the measurement should be completed before crystallization of amorphous material or chemical decomposition has started, which can be done by employing fast scan rate.

8.6.1.4 Microscopic Technique

Cross-polarized microscopy is one of the most powerful but largely ignored techniques in amorphous formulation characterization in comparison to more sophisticated instrumental techniques, presumably due to the requirement of experience in the interpretation of data and limited information in this regard. Nevertheless, many researchers have used the cross-polarized microscope to study the kinetics of crystallization and to predict the stability of amorphous systems (Taylor and Zografi 1997; Yu 2001). As stated earlier, the cross-polarized microscope utilizes differences in birefringence between crystalline and amorphous systems, as amorphous material does not exhibit birefringence.

8.6.1.5 Other Techniques

Water vapor sorption can be used to discriminate between amorphous and crystalline materials if hygroscopicity is different, and in the absence of interferences.

Isothermal microcalorimetry was one of the earliest techniques used to study amorphous systems with remarkable sensitivity. This is based on the principle that enthalpy changes at constant temperature and relative humidity are associated with (re)crystallization of amorphous material. However, this technique is extremely sensitive to many operational conditions, which makes it difficult for routine use.

8.6.2 Determination of Molecular Arrangement in Amorphous Systems

As discussed earlier in this chapter, an ideal formulation is one that provides the maximum physical stability over the intended period and maintains supersaturation while the drug is being absorbed. The ideal amorphous formulation can be designed by judicious selection of polymer(s) and drug loading in response to the specific physicochemical properties of the drug molecule. Physically, the maximum stability and optimal performance are achieved when drug molecules are molecularly dispersed in a polymer matrix with appropriate intermolecular interactions between the drug and the polymer(s). Therefore, in order to make a proper assessment of “structured development approaches,” it is extremely important to get insight into the amorphous formulation to determine how the drug molecules are arranged and distributed within the polymer matrix.

The most commonly used techniques are vibrational spectroscopy such as IR and Raman spectroscopy. IR spectroscopy has been extensively used to study the molecular arrangement of drug and polymer and their interaction. Kaushal et al. studied the differences between intermolecular interactions in amorphous and crystalline phases of celecoxib, valdecoxib, rofecoxib, and etoricoxib using FTIR (Kaushal et al. 2008). Konno et al. studied interactions between amorphous felodipine and PVP, HPMC-AS, and HPMC using FTIR (Konno and Taylor 2006). It was concluded that hydrogen-bonding between drug and polymer were an integral part of amorphous formulation stabilization. Solid state NMR has been increasingly used to study molecular interaction between amorphous drug and polymer.

X-ray powder diffraction using pairwise distribution function has been employed to investigate the local structure of amorphous formulations (Bates et al. 2006). AFM can provide geometric distribution of a drug in a polymer matrix at a nano-scale, furnishing valuable information on mixing and demixing processes. It is true that the various techniques discussed above can provide a myriad of information on amorphous formulations. It is, however, the keen observation and insights of the well-trained scientist that provide the most valuable understanding of amorphous formulations (Fig. 8.8).

Fig. 8.8 Calibration model in solid state

8.6.3 Dissolution Method for Amorphous Formulations

Development of meaningful dissolution methods for kinetically unstable systems of poorly soluble drugs is a daunting task. It requires a careful consideration of physiologically relevant conditions, demonstrating adequate discriminating power, and predicting in vivo performance. A perfect sink condition will not help to ascertain the ability of a system to maintain supersaturation. However, an overly nonsink condition may result in overdiscrimination and potential elimination of a viable formulation. There are several publications related to dissolution of amorphous formulations (Law et al. 2004; Chan and Kazarian 2004; Doherty and York 1987; Janssens et al. 2010). The effect of polymer type on the dissolution rate of amorphous systems has been described by Taylor et al. (Konno et al. 2008).

Unlike as for crystalline APIs, equilibrium solubility cannot be determined for amorphous materials because, at equilibrium, drug solubility using the crystalline or the amorphous form is similar, by definition. Therefore, the method has to determine the kinetic solubility in physiologically relevant conditions.

The kinetic solubility of amorphous material can be determined in bio-relevant or aqueous medium with or without surfactant. If we accept the fact that precipitation follows supersaturation, then solubility of amorphous material at a 30–60 min time window, or at the peak of the upward slope could be used for determination of kinetic solubility. This is illustrated in Fig. 8.9, where the C_{\max} at the T_{\max} could be used for kinetic solubility determination.

Based on the kinetic solubility, dissolution conditions can be varied with regard to dose, volume of dissolution medium, and surfactant concentration of dissolution medium for screening amorphous formulations. A dose representing 100% saturation in the dissolution medium can provide an efficient way to screen formulations. For example, for a drug with 50 $\mu\text{g}/\text{mL}$ kinetic solubility, a dose of 50 mg in 1,000 mL would represent 100% saturation. However, a higher dose in a similar medium will represent greater than 100% saturation and may cause an unnecessary stress in the dissolution medium. In the same way with the fixed dose of 50 mg, a dissolution medium not providing 100% supersaturation will also cause similar stress in the medium.

Fig. 8.9 Schematic representation for kinetic solubility determination for amorphous materials

Fig. 8.10 Effect of surfactant concentration on the dissolution behavior of amorphous solid dispersion and supersaturation

A dissolution medium representing 100% saturation is the most efficient way of screening formulations. Additionally, a formulation maintaining supersaturation for at least 2–3 h (physiologically relevant) would represent a viable formulation. On the contrary, a formulation maintaining supersaturation for less than 60 min would need careful evaluation.

For a research compound, we have determined kinetic solubility at 60 min and performed dissolution at different levels of saturation using varying surfactant concentrations. As shown in Fig. 8.10, using the dissolution medium at more than 100%

saturation (surfactant concentrations A, B, and C), the same formulation exhibited different slopes in the dissolution profile. However, at 100% saturation (surfactant concentration D), at least 4–6 h of supersaturation were maintained. This formulation provided dose proportional exposure in animals and humans suggesting that a dissolution condition corresponding to 100% supersaturation (maintained over 2–3 h) may simulate *in vivo* conditions fairly well. These results suggest the need to develop a dissolution method that simulates conditions corresponding to 100% saturation using kinetic solubility data. This can be achieved by adjusting the dose, dissolution volume, or composition of the dissolution medium. The dissolution profile is further characterized for maximum amount of drug dissolved (C_{\max}), time to achieve the maximum concentration (T_{\max}), and the duration for which it is maintained.

8.6.4 Stability Prediction

The goal for amorphous formulation stability is to maintain long-term physical stability with respect to solid state properties and maintain supersaturation during the time course of the dissolution process mimicking the *in vivo* dissolution window, which is generally about 2–4 h. The key to understanding stability is to understand that molecules in an amorphous system can have significant molecular motion both above and below the glass transition temperature. Molecular motion in the form of translational and rotational diffusion can generally be described in terms of molecular relaxation time or annealing time. In addition, the effect of water on molecular mobility and stability must be accounted for. Water can exist in an amorphous state with a T_g of about -138°C (135 K). As such, water can reduce glass transition temperatures of amorphous systems substantially. The effect on T_g can be more pronounced for partially amorphous systems. In such cases, most of the water will be located in the disordered region and the T_g in that region will be considerably lower (Marsac et al. 2010; Rumondor et al. 2009a, b). Temperature naturally has a direct effect on molecular mobility. Molecular mobility is generally considered one of the key factors in determining amorphous system stability. Molecular motions are characterized by the time dependence of bulk properties such as volume or enthalpy. Various parameters used for prediction of stability of amorphous system are mean relaxation time constant, relaxation time distribution parameter, and crystallization rate constant. The molecular relaxation process is sometimes characterized by the empirical Kohlrausch–William–Watts (KWW) equation. Specifically, using DSC it is possible to estimate molecular mobility by measuring heat capacity or the scanning rate dependence of T_g .

In spite of intensive research to predict the stability of amorphous systems through molecular mobility concepts, the prediction of physical stability is rather unpredictable. Often, physical instability occurs in a nonlinear fashion after varying induction periods. Although the stability of amorphous systems is not predictable,

one can use accelerated stability condition of severe humidity and temperature to rank order the formulations. A commonly used accelerated stability condition for formulation screening is 40°C/100% RH. In this case, amorphous solid dispersions are subjected to stress conditions and are evaluated by PXRD, FTIR, and DSC analysis. In addition, the suspension stability that is performed to enable the use of amorphous dispersion for toxicology studies is also helpful to assess physical stability. For toxicology purposes, the preferred vehicle is the one having the lowest solubility for amorphous solid dispersion and should maintain amorphous form stability for up to 4 h at room temperature.

8.7 Overall Summary

In this chapter, we have proposed a structured development approach for amorphous formulations based on sound physicochemical principles of the drug and the polymer with the goal of maximizing success rates and reducing risks. The proposed approach consists of a comprehensive evaluation of the drug substance and polymer properties and understanding the basic principles to help design amorphous dispersions that provide consistent *in vitro* and *in vivo* performance. The assessment of basic physicochemical properties of drug substance including its thermal behavior (T_g , T_m , stability, and recrystallization), hydrogen-bond acceptor and donor groups, molecular weight, hydrophobicity, solubility parameters, solubility (aqueous and organic solvents), and hygroscopicity forms the basis of determining the degree of difficulty a molecule may present in converting to and maintaining an amorphous form. Likewise, a thorough understanding of the physicochemical and mechanical properties of polymers will help in the determination of the suitability of polymer(s) for a given drug for an amorphous solid dispersion. Understanding the solubility, miscibility, and interaction parameters will help in ranking the polymers and in selecting possible drug loadings for an amorphous solid dispersion. The miniaturization techniques (the SPADS approach) help in the selection of specific polymers and drug loads for maximum solid-state stability and supersaturation. The systematic evaluation of physicochemical properties of drugs and polymers with respect to thermal behavior and solvent and aqueous solubility and stability guide the selection of appropriate processing techniques for amorphous solid dispersions. Different instrumental techniques are presented to characterize and quantify the crystallinity and for understanding the phase behavior of amorphous solid dispersions. The use of more than one technique is preferred to establish confidence. Amorphous formulation stability is difficult to predict; however, the accelerated test at 40°C/100% RH and the suspension stability test provide a useful insight into the stability of these amorphous systems. Similarly, approaches are presented to help develop appropriate dissolution methods based on kinetic solubility and consideration of the supersaturation level to avoid false negatives. Finally, a flowchart shown in Fig. 8.11 is proposed as a blueprint for structured development of amorphous formulations.

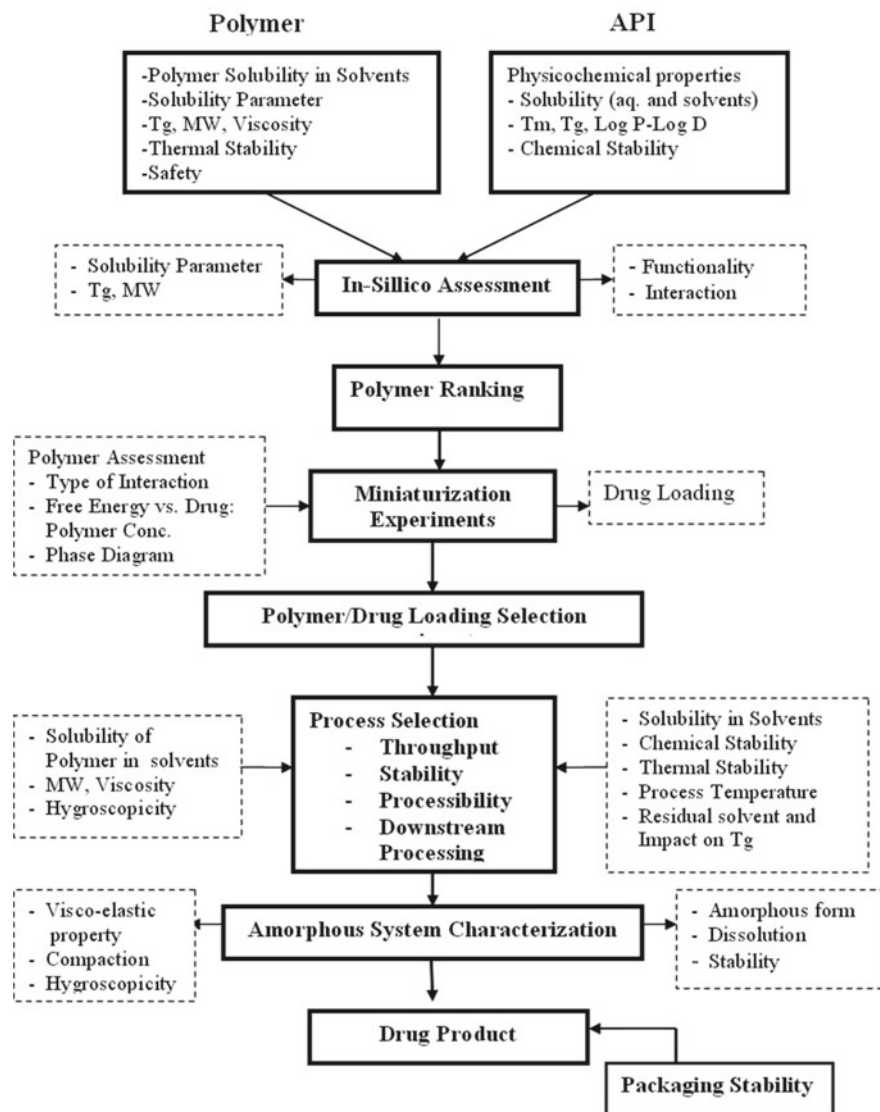

Fig. 8.11 Structured development approach for amorphous formulation development

Chapter 9

Melt Extrusion

James C. DiNunzio, Feng Zhang, Charlie Martin, and James W. McGinity

Abstract Driven by the need to enable therapies of poorly soluble compounds through the generation of amorphous solid dispersions, pharmaceutical scientists have adapted a number of technologies from other industries to provide reliable and robust drug product manufacturing. Melt extrusion is an example of such a technology. Originally developed in the plastics industry over a century ago, it has been applied to pharmaceutical systems over the last three decades to generate some of the most cutting-edge delivery systems seen in the industry to date. The well-characterized nature of the process provides for ease of scale-up and process optimization, while also affording benefits of continuous manufacturing and adaptability to process analytical technology in an ever-changing regulatory and fiscal environment where manufacturing efficiencies must be maximized to reduce cost and improve product quality. This chapter details the basic engineering principles of the melt-extrusion process and provides a fundamental understanding of formulation development of melt-extruded solid dispersions for bioavailability enhancement. Several recent case studies are also described to highlight the applicability of the technology to developmental and marketed products within the industry.

9.1 Introduction

Extrusion has been a well-established industrial manufacturing technology for over a century, spanning applications from commercial wire formation (Dover 1902) to synthetic wine cork production (DiNunzio et al. 2010a) and even serves as one of the unit operations in the manufacturing process for McDonald's famous McRib sandwich (Hanna et al. 1996). Available in multiple variants based on equipment geometry and processing temperature, twin-screw melt extrusion has emerged as a viable technology in the pharmaceutical industry for the production of solid dispersions (Leuner and Dressman 2000; Breitenbach and Mägerlin 2003; Serajuddin 1999). Providing advantages of continuous processing and ease of adaptability to in-line analytical technology, twin-screw melt extrusion has been extensively utilized in several pharmaceutical technologies, including: solid dispersion production, advanced device manufacturing, continuous melt granulation, and the development of controlled release products for oral delivery (Breitenbach 2002; Crowley et al. 2007; Repka et al. 2007, 2008). While each particular application currently presents unique opportunities in pharmaceutical development, this chapter is dedicated to a discussion of amorphous solid dispersions and advanced delivery drug products to address solubility limitations. Covered within this chapter is a detailed discussion of the fundamental theory of hot-melt extrusion, addressing process considerations and also describing the critical aspects of formulation design for producing stable amorphous solid dispersions. Major case studies covering the most recent applications of melt extrusion to provide formulation intervention and enable therapeutic delivery are presented, with these examples providing improved bioavailability through solubility enhancement and targeted delivery. In all cases, these discussions focus on the most current applications of hot-melt extrusion for pharmaceutical production, demonstrating the applicability of the technology to enable drug product development while highlighting areas of potential future growth.

9.2 Equipment Design and Engineering Principles

Twin-screw melt extrusion was developed during the 1930s and has been extensively studied for a number of polymer processing operations (Mollan 2003; Thiele 2003). Today, the theory of the technology has been well described and the processing equipment extensively developed. Based on decades of research and recent application of the technology to the production of pharmaceutical products, one major facet of design has become evident: formulation and process go "hand in hand" to yield desired critical product attributes. Melt viscosity and solubility of a formulation directly influence processability factors such as motor load, pressure, and residence time distribution (Repka et al. 1999; Schilling et al. 2007). Similarly, screw design, throughput, and die geometry may impact solubilization and degradation rates of the formulation due to microenvironmental changes within the control volume (DiNunzio et al. 2010b; DiNunzio 2010). During early development using

material-sparing approaches, it is critical to understand the interplay of formulation and process variables to allow for rational design. Identification of primary factors governing critical product attributes and the ability to address issues associated with their control are crucial to establishing a basic formulation and process to support developmental activities. In later development, full optimization using a quality by design methodology requires a true understanding of the complex formulation–process interaction in order to establish a robust and highly efficient design space to support routine market production. Given that early development and later-stage optimization are both driven by the interplay between formulation and process, this section describes the fundamental engineering aspects of hot-melt extrusion.

Pharmaceutical melt extruders are classified using several fundamental characteristics of the equipment, including the number of screws, the direction of rotation of the screws (co-rotating or counter-rotating), the degree of element intermeshing, and the screw size as a function of diameter. The number of screws determines the application of the equipment for pharmaceutical production. Single-screw extruders are primarily used to provide more consistent pumping (Kim and Kwon 1996a, b; Luker 2003). Example products prepared by single-screw extrusion include oral filaments, catheter tubes, and multi-layer films. Twin-screw extruders are frequently used in compounding applications due to their higher mixing efficiencies (Thiele 2003; McGinity et al. 2007). For twin-screw extruders, the direction of rotation and type of intermesh play a major role in the equipment efficiency and purpose. Extruder screws relative to one another may either be operated in a co-rotating or counter-rotating configuration, with co-rotating units having both extruder screws rotating in the same direction. This geometry is also associated with opposing surface velocities in the intermesh, which is more commonly known as a self wiping design. In this system the rotational motion of one screw wipes material from the other to further convey material down the length of the barrel. In the case of counter-rotating twin screw extruder, elemental designs are available in both an intermeshing and non-intermeshing format. Counterrotating intermeshing designs can be associated with the production of heat sensitive materials. This type of design provides advantages for the production of heat sensitive materials where a tight residence time distribution may be an issue. For the purposes of this chapter, equipment discussion will focus primarily on the intermeshing co-rotating twin-screw extruder.

While generalized as a single-unit operation, melt extrusion is actually a combination of multiple operations, each contributing to the operational performance. Fundamentally, melt extrusion is divided into five basic steps (Schenck et al. 2011):

1. Feeding of raw materials
2. Conveying
3. Melt compounding
4. Devolatilization
5. Pumping
6. Shaping

Most modern twin-screw extruders offer a modular design that allows scientists to incorporate these basic operations in any sequence desired and with as many

repetitions as needed to achieve the desired product attributes. This modularity of the process gives rise to a need to address the general description of the equipment. A twin-screw extruder consists of several basic components, each of which participates in the cumulative manufacture of the drug product. These parts are:

1. Gear box and motor
2. Barrel with heating elements
3. Shafts
4. Screw elements
5. Dies

9.2.1 Basic Equipment Description

9.2.1.1 Gearbox and Motor

The gearbox and drive motor provide the mechanical energy to turn the shafts during processing. Size of the motor is correlated with the overall size of the extruder, most commonly referred to by the diameter of the screws. For example, an 18-mm extruder has 18-mm screws and barrel bores, while a 50-mm extruder has 50-mm bores and screws, noting that there is a clearance between the screws and barrel bore. Additionally, many smaller research units offer the flexibility to change from co-rotating to counter-rotating designs based on the gearbox configuration, which allows for added versatility during development. Different types of elements are utilized based on the desired configuration and mode of operation. This also illustrates how aspects of the extruder engineering may be tuned to the desired application.

9.2.1.2 Extruder Barrel

Extruder barrels are temperature-controlled regions that house the screws and provide a delineation of external control volume during production. The length of the process section is frequently described in terms of the length to diameter (L/D) ratio, with greater L/D values indicating a longer barrel. The L/D ratio is defined by dividing the overall length of the process section by the diameter of the screws. For most pharmaceutical compounding operations L/D values ≤ 40 are used, while reactive and devolatilization extrusion operations utilize even longer process sections. The barrel section of a twin screw extruder is available in two basic configurations: sequential blocks and clamshell, providing unique advantages and disadvantages. Clamshell designs allow for the barrel to be opened along the backbone of the system, analogous to opening a clam and hence the name of the design. This allows users to easily access all points of the barrel which can facilitate sampling and cleaning activities, which can be particularly advantageous during early development by allowing for regional determination of process performance without

Fig. 9.1 Types of block sections from a segmented barrel design, moving from *Left to Right*, solid feed, liquid feed, side feed, vent, and closed block

removal of the screws from the barrel. Modular interchangeability with these systems is often more limited when compared to the sequential block design. Also, leakage along the barrel seam is possible for high-pressure operations which is less likely with other barrel geometries. Temperature control is also generally not as precise with the clam shell design. In the case of the sequential block design, modularity of the system and temperature control are improved but cleaning and locational sampling along the length of the extruder may become more difficult due to cross-contamination of zones during the screw-removal process.

Along the barrel, five critical zone types are observed: solid feed, liquid feed, side feed, venting, and closed segments. These sections are shown in Fig. 9.1. Each section serves specific functionality, allowing for multiple-unit operations to be achieved when combined with the desired screw design.

Feed zones are positioned as the most upstream point of the process and allow for the introduction of solid material into the system. For most pharmaceutical operations, the feed rate of raw materials to the extruder will be controlled by a gravimetric feeder which uses a loss-in-weight feedback loop to regulate mass flow from the unit and into the extruder via a powder hopper. For pharmaceutical operations, feeding is most commonly conducted in a “starve fed” mode, meaning that the rate of material addition into the feed zone is less than the rate material is removed by the extruder screws into the barrel (Schenck et al. 2011). In some cases, poor flow of material may result in bridging of material in the feed zone, limiting the ability to manufacture at steady state. Off-gassing of residual moisture and solvents may also occur through the feed zone where the vapor phase condenses onto the powder, reducing flowability and contributing to bridging. To address these issues, options

Fig. 9.2 Schematic diagram comparing standard 40:1 extruder to 40:1 extruder with side stuffer for incorporation of a heat-sensitive API

are available for treating surfaces in the solid feed region with Teflon™ and other coatings to aid material flow. The implementation of baffled hopper designs can limit off-gassing in these regions and increase feed rates into the system. “Crammer” feeders can also be used to increase the feed density and increase attainable throughputs. Options for feed rate improvement should be considered for formulations having a low-density, high-moisture content and/or heat sensitivity issues.

Liquid feed points allow for the introduction of liquids or molten materials into the extruder via the use of a gear pump or other appropriate pumping system (Steiner 2003). Liquid injection nozzle designs feed material at the intermesh of the two screws, allowing the liquid component to begin mixing with the process stream. Coupled with the corresponding placement of mixing elements for distributive mixing, systems may be designed to incorporate liquid contents in excess of 50% total formulation weight by using a series of liquid injection – mixing regions along the length of the extruder. Commonly used for the addition of liquid phase or semi-solid materials such as triethyl citrate and vitamin E TPGS, respectively, these systems can significantly improve production efficiency by eliminating the need for premixing steps such as wet or melt granulation prior to extrusion.

Side-stuffing options allow for the addition of materials at a later point along the barrel (Steiner 2003), as illustrated in Fig. 9.2. A side stuffer is a co-rotating, intermeshing twin screw auger that “pushes” material into the process melt stream. This process serves several functions, allowing for avoidance of the high shear region associated with melting and reducing residence time exposure for heat-sensitive materials. When combining materials using side stuffing, feed control, and proper screw design are essential to achieve the appropriate combination of distributive and dispersive mixing without substantial perturbations in feed stream rates. Such inadequacies have the potential to drive heterogeneity and increase the likelihood for residual crystallinity of an amorphous system. During side-stuffing operations, it is also necessary to provide sufficient venting. Material streams added at upstream locations may also

contain residual moisture or solvents that may become volatilized during production. These are removed at the venting locations into the process section.

Vent zones provide essential function during extrusion, yielding a pathway for removal of volatile materials from the manufacturing process, including residual moisture, organic solvent, and, in some cases, drug substance. Removal of these materials can be intentional, as is generally the case with water or other solvents but, in some cases, such as with drug substance, may be unintentional. Furthermore, the venting process may also be performed under vacuum and may occur at a series of points along the length of the extruder. Using a series of venting locations, it is possible to remove substantial quantities of volatiles from the extrudate, as was done by Schenk (2010), when utilizing melt extrusion to achieve solvent removal from drug-substance feedstocks while simultaneously preparing amorphous solid dispersions. Unintentional venting, particularly of pharmaceutical formulations, may also occur for certain drug substances. Although a rare phenomenon, this can easily be corrected by closing vent ports that allow for off-gassing of the drug substance. Unintentional off-gassing may also occur in the solid feed region, resulting in aggregation and bridging of the powder feed material. This is due to the relatively high moisture content of many pharmaceutical polymers. When fed into the extruder, the materials will be heated beyond the boiling point of water, liberating the residual moisture. If a pathway for moisture removal is not present along the barrel length, the system will off-gas via the feed port. Feed hoppers with baffles may address these issues, as can placement of a vent port near the solid feed hopper.

Closed barrel zones generally represent the majority of processing length for a pharmaceutical extruder and are the site where high-pressure compounding operations are located. These regions provide a closed system and maintain molten material within the control volume of the unit. For operations such as mixing, kneading, or shaping through the die, fill ratio within that incremental space will approach unity and drive a pressure buildup. It is essential that all pressure operations be performed within the confines of the closed segments to prevent unwanted outflow of material from the extruder. For example, placement of vent zones too close to kneading sections may result in vent flooding due to the pressure buildup (Steiner 2003). In general, this type of behavior is prevented through the use of screw design to transition material flow while providing sufficient length between the vent and kneading section. Alteration of screw speed and feed rate can also be used to alter fill in the extruder to reduce outflow from vent ports.

Design of the barrel sections is highly dependent on the number of operations to be performed. For example, a hypothetical system requiring only compounding of drug and polymer, moisture removal, and shaping can easily be conducted in a 25:1 configuration. Meanwhile, a 40:1 configuration would be more appropriate for a more intensive process which requires plasticizer injection, compounding of polymer with plasticizer, drug addition via side stuffing, compounding, and moisture removal and shaping. If reactive extrusion or substantial devolatilization is required, then a process length of 60:1 or greater may be necessary. Careful consideration based on the goals of the process will ultimately determine the requirements for process length.

Fig. 9.3 Shaft designs for pharmaceutical twin-screw hot-melt extruders

9.2.1.3 Screw Elements & Shafts

Screw shafts, upon which the elements are assembled, are the backbone of the manufacturing process and experience high torque during production. The magnitude of torque depends on the processing conditions used during extrusion and types of elements used to assemble the screw. Critically, screws must be capable of transferring load from the motor to the elements to allow for successful processing. This transfer of energy occurs through the shaft–element interface, to which there are three basic types: keys, splines, and asymmetric splines. Shaft types are presented schematically in Fig. 9.3. Keyed shafts consist of a single key that couples to the shaft and element. During processing, the entire load is transferred along the key, resulting in a system that generally has the lowest maximum torque. Splined shafts present an increased surface area to transfer load to the elements and also allow for a greater maximum torque when compared to a keyed shaft. Asymmetric shafts have a similar design to a conventional spline shaft, but have an intentional curve to each spline to distribute the force tangentially to the direction of rotation while conventional splines have multiple force vectors. By developing a system capable of presenting a single tangential force vector, shafts are able to absorb even greater torque levels which allow for greater throughput for a wider range of potential formulations.

9.2.1.4 Screw Elements

Screw elements for pharmaceutical twin-screw extrusion are classified into three basic categories based on function: zoning elements, mixing elements, and conveying elements (Thiele 2003; Steiner 2003). Each type of element is included on the screw to impart a specific function and drive the formation of a product having the desired product attributes. Furthermore, all elements are defined by several basic descriptors which define the geometric properties of the elements and their resulting impact on material, as shown in Fig. 9.4. Within twin-screw extruders, lobal pools result due to the rotational movement of the screw. Material follows the perimeter path along the cross section of the barrel in the screw channel. Shear reaches a

Fig. 9.4 Illustration of critical geometric descriptors of twin-screw extruder elements

maximum value within the overflight and lobar pool regions, while channel regions exhibit a shear minimum (Thiele 2003). This unique mixing pattern provides greater efficiencies than single-screw extruders and allows for effective compounding on the twin-screw extruder platform.

Conveying elements provide a mechanism for moving material from upstream regions to downstream regions within the extruder via drag flow that provides a forward moving thrust (Tzonganakis 1989; Tadmor 1966). Forwarding is generally directly proportional to rotational velocity and pitch angle. Within this class of elements, the units are defined based on a series of geometric characteristics illustrated in Fig. 9.5. Generally, feed regions contain elements with the longest pitch to maximize conveyance from the zone, while transitions to pressured zones will be supplemented with a decrease in pitch.

Mixing elements are used to increase mixing in localized regions along the length of the extruder. Frequently used in combination with liquid injection, these elements serve to evenly distribute materials of varying viscosities due to the deformation and elongational mixing which occurs as a result to the design of the element and flow field resulting from the intermesh of the second screw (Steiner 2003). Vane design on the mixing element determines the direction of conveyance, with elements available in forwarding, neutral, and reversing direction.

Kneading elements, the most commonly used type of mixing element, are included along the length of the screw to provide distributive and dispersive mixing, with the magnitude of mixing determined by the geometry of the element. Consisting of offset paddles, the key parameters regulating the degree of mixing are the offset angle of the paddles (30° , 60° , and 90°) and the length of the paddle. Increasing offset angles of the paddles increases the mixing intensity and also lead to greater increases in localized temperature (Steiner 2003; Tadmor 1966). Direction of paddle offset determines the level of conveyance, leading to elements with forward or reversing natures. Elements with a 90° paddle offset are neutral conveyance.

Fig. 9.5 Geometric descriptors for conveying elements

Increasing the width of the paddle segments provides a greater level of dispersive mixing when the overall element length is maintained fixed. For most pharmaceutical applications, the maximum number of kneading segments will not exceed two four-paddle sequences due to the shear-sensitive nature of the materials used in compounding and the limited residence time requirements to achieve target product properties.

9.2.1.5 Dies

The next step of an extrusion operation is to shape the compounded material into a shape for downstream processing. For pharmaceutical production, the most commonly used geometries are the rod or film type, with these materials collected on air quench conveyors, film belt systems, or chill roll-knibbler systems. Pellets can also be produced by a die face pelletizer. In general, strict geometric shaping from extrusion for oral delivery systems is not required because the process trains will mill the extruded material into a fine powder for further processing. In select applications, such as medical tubing formation, annular dies are utilized to generate hollow or coated filaments.

The importance of die geometry is twofold for pharmaceutical manufacturing. When processing directly shaped materials, accurate control of part geometry can directly impact final part compliance of target product attributes. For example, pulsing from the die during belt pulling applications may lead to variable filament geometries and control difficulties during production. The other major area of

influence is with heat- and pressure-sensitive materials. Cross-sectional area and internal geometry of the die relative to the mass flow rate determines the pressure buildup in the die region, which can directly influence the performance of pressure-sensitive products. Additionally, many pharmaceutical active ingredients and polymers are heat sensitive. Depending on the screw design utilized, pressure buildup can be correlated to localized temperature increases where the temperature increases by up to 1°C for every 30 psi generated (Todd 1995). For common pharmaceutical applications where pressures are generally 300–600 psi at the 18-mm scale, this can result in local temperature increases of 10–20°C due to viscous dissipation during transit. When processing heat-sensitive products, changes to die geometry to minimize pressure buildup can reduce impurity formation during production. Pressure generating devices, such as a gear pump, can be mated to the twin screw extruder to help manage pressures, and melt temperature.

Other more general issues with the quality of extruded products are die swell, shark skinning, and melt fracture (Perdikoulis and Dobbie 2003). These defects are presented schematically in Fig. 9.6. Die swell is caused by the entropic restriction placed on material through the die that causes polymer molecules to orient parallel to the direction of flow (Perdikoulis and Dobbie 2003; Wang and Drda 1997). Upon exiting, the polymer chains re-orient to the natural random coiled structure due to elastic recovery, resulting in swelling of the material. Shark skinning is the appearance of surface roughness of the extrudate material on exit from the die (Kulikov and Hornung 2001). The magnitude of these defects directly related to both material properties and die geometry. Originating from factors related to acceleration of the surface extrudate layer, manipulation of material linear velocity, die landing length, die surface coating/polishing and temperature can all be used to reduce shark skinning in production (Perdikoulis and Dobbie 2003; Kulikov and Hornung 2001).

9.2.1.6 Feeders

During manufacturing runs, a continuous stream of material must be supplied to the extruder when operating at steady state. This is achieved through the use of gravimetric or volumetric feeders to meter solid, liquid, or gaseous materials into the process section. A gravimetric feeder is identical to a volumetric feeder except the feeder is situated on a load cell that is used to modulate the feed mechanism to maintain a constant mass flow rate to the extruder. Selection of feed screw geometry can play a significant role in process uniformity, reducing the avalanching and pulsing behavior of the feed stream (Schenck et al. 2011; Doetsch 2003). Examination of avalanching behavior shows that the period of pulsing is a function of the flight design. For example, transition from a single-flight to a dual-flight system operated at 60 rpm reduces the pulse period from 1 to 0.3 s. Further monitoring of material feed during production with gravimetric feeders is achieved using feedback control loop which monitors real-time weight loss while also adjusting

Fig. 9.6 Examples of melt-fracture appearance

screw speed to maintain a consistent feed rate. Low bulk density and poor-flowing materials can present unique feeding challenges even within the gravimetric feeder. Self-wiping screw designs and nonintermeshing undercut designs can improve material throughputs, while driven agitators can minimize powder bridging during manufacture.

In the case of liquid feed streams, control can be achieved using volumetric or gravimetric systems depending on the feed rates and material properties. These systems are generally closed systems that feed directly into the process section through the use of liquid injection ports. Systems can be designed to perform at ambient or elevated temperatures, which allows the addition of low-melting-point solids as liquids into the system. Similar to gravimetric solids feeders, liquid feeders must be able to provide a consistent and reproducible feed stream at steady state, which can be ensured through proper equipment and process design. Nozzle restrictions ensure that liquid is fed into the extruder at sufficient pressure to prevent clogging (Schenck et al. 2011). Further reduction of feed variability is achieved through the use of the gear-type pumping systems which are not subject to significant flow-rate variations seen in other pump designs. Smart control systems that are able to assess changes to processing and feed conditions can also help to compensate for drift which occurs over extended runs, thereby allowing the system to maintain steady state.

While not extensively used in pharmaceutical applications, supercritical fluid injection has been applied to pharmaceutical processes (Verreck et al. 2006a, b, 2007; Lyons et al. 2007). In general, the feedstock will be a supercritical liquid and will use metering and injection systems where critical pressures help to add material into the process. Applications will also be supported by screw design, where melt seals will be formed at various points along the barrel to prevent off-gassing during manufacture.

9.2.2 Hot-Melt-Extrusion Processing

Production during hot-melt extrusion is a function of formulation and process, each playing a key role with substantial interdependence. As a continuous process, melt extrusion can be viewed to have two specific operational modes: dynamic and steady state. In the dynamic mode, a mass balance will not be achieved leading to accumulation. This stage occurs during start-up or major system perturbations and represents only a very small sequence of the overall run. The majority of the process will be conducted at steady state where a mass balance is achieved and no accumulation occurs. While transient processing is difficult to model, steady-state operation of extrusion processes has been well described. In addition to the engineering principles, the process may also be described from the perspective of the formulation based on the drug-substance melting temperature in relation to the processing conditions. This section provides fundamental engineering and process concepts as related to pharmaceutical production using hot-melt extrusion.

9.2.2.1 Steady-State Processing and Production Feedback

During extrusion operations, several fundamental engineering principles describe the behavior of the system. As mentioned previously, most twin-screw melt-extrusion applications are conducted in a “starve-fed” manner where material addition into the system is controlled by the feeder (Thiele 2003). In such cases, the feed rate is independent of the extruder screw speed and the rate of material conveyance into the extruder is greater than the rate at which material is being provided to the system. Establishing a control volume around the process section of the extruder, as illustrated in Fig. 9.7, allows for the establishment of a mass balance that accounts for all possible addition and removal streams from the process. When operating at steady state, a mass balance is achieved where the mass into the system is equal to that leaving the system.

In the majority of applications, 100% fill of the extruder will not be achieved across the length of the process section (Todd 1995). Most screw elements will be starved, with only 100% fill achieved in the higher-pressure regions leading to kneading/mixing elements and the die. High levels of fill will also be achieved in the kneading/mixing sections themselves because of the limited conveyance provided by these types of elements. As such, one can also define a fill volume within the extruder system and can correlate residence time as a function of mass flow rate and volume. It is important to note that residence time is not a discrete value but a distribution which can be described in average or cumulative terms for any fraction of material. A hypothetical residence time distribution and cumulative plot are shown in Fig. 9.8. For pharmaceutical compounding applications, the residence time and corresponding distribution determine the ability to achieve the desired target product attributes without excessive degradation of the materials. In some cases, these attributes will be defined by the mean residence time ($\bar{\tau}$), whereas other applica-

Fig. 9.7 Steady-state control volume for hot-melt-extrusion operations

Fig. 9.8 Hypothetical residence time distribution profile plotted as discrete value and cumulative curves

tions, such as heat-sensitive material processing, may best be defined by the time for 99% of the material to leave the extruder ($t_{99\%}$). For early development work, one can easily manipulate residence time and distribution by changing feed rate and screw speed. Changes to screw design, temperature, and formulation can also have a substantial impact on residence time distribution and often prove to be useful parameters to control during development (Schenck et al. 2011; Todd 1995; Ganjyal and Hanna 2002). A summary of these process parameters and the corresponding impact is provided in Table 9.1. For example, increasing screw speed provides for moderate reductions in \bar{t} but can provide more significant reduction of $t_{99\%}$ values due to the narrowing of the distribution observed. Alterations to temperature and formulation directly impact product viscosity during production, altering the fluid dynamics of the process.

Beyond understanding the overall residence time within the system, melt residence time can play a critical role in product performance. Melt residence time is defined as the time during which material exists within the molten state. As material

Table 9.1 General impact of process parameters on residence time of melt-extruded products

| Parameter | Magnitude | Effect on residence time | |
|----------------|--------------|--------------------------|--|
| | | Variable, RTD Effect | Description |
| Process length | Minor | ↓, ↓ | Reducing will generally result in shorten mean residence time |
| Mass flow rate | Major | ↑, ↓ | Increasing will result in shorter mean residence time |
| Screw design | Major | ↓, ↓ | Reduced number of mixing/kneading section will contribute to shorter mean residence time |
| Screw speed | Intermediate | ↑, ↓ | Increasing will generally mean shorten residence and narrow residence time distribution |
| Die opening | Minor | ↑, ↓ | Generally minimal impact. Larger orifice will generally reduce residence time. Also contributes to lower localized temperatures. |
| Temperature | Intermediate | ↑, ↓ | Increasing will generally lower viscosity and reduce residence time. Some formulations may thin excessively limiting flow |
| Formulation | Intermediate | Dependent | Formulation determines viscosity and which can impact residence time and distribution |

enters the system, it displays a specific set of solid-state characteristics and has a defined temperature which is generally that of the ambient environment. During conveyance from the feed zone to downstream regions within the extruder, mechanical energy is imparted into the material along with conductive heat transfer from the barrel wall. This energy, 80–90% of which originates from the energy provided by the screws, drives a temperature increase of the material (Rauwendaal 2001). At some point along the length of the extruder, the material transitions from solid to melt resulting in peak observed shear and a well-delineated change of flow characteristics. This behavior is generally due to one or more of the components melting or achieving a temperature greater than the glass transition temperature. At this point, material may be considered a melt and the melt residence time begins. It is also at this point that the polymer begins to exhibit properties characteristic of a solvent as a result of lower viscosity and greater molecular mobility. As the molten dissolution process begins, drug substance will convert from crystalline to amorphous, defining the time zero point for the dissolution process and signaling the point at which materials begin to become more susceptible to degradation due to the absence of crystalline morphology, which can inhibit certain decomposition processes. Exposure to the high-energy environment also increases rates at which these reactions occur. It is not surprising to see that melt residence time plays an important role in the production of high-melting-point compounds and heat-sensitive compounds. In these cases, optimization of barrel temperature can be used to control

the size of the melt region along the length of the screw. Reducing barrel temperatures in concert with screw design and screw speed can increase heat transfer rates from the system and help to lower localized temperatures within the process (Todd 1995). At a critical threshold, barrel temperature reduction may become too great and result in an inability to process or render target product properties.

During manufacture, the majority of energy is imparted due to the mechanical input provided by the screw, which manifests itself as shear and viscous dissipation of frictional energy resulting in temperature increases. Viewing the extruder process section as a stationary boundary and the rotating screw as a moving boundary, the shear rate of the molten polymer can be defined as a function of geometry and screw speed, as shown in (9.1). Further understanding of the shear stress applied to the system is obtained as the product of shear rate and viscosity, described in (9.2). Given that the shear rate and shear stress are functions of the clearance geometry, a profile will be obtained across the length of the process section as a function of elemental design. Detailed knowledge of peak shear and cumulative shear experienced during production is necessary for successful process optimization and scale-up. Of further importance to the design of the process is the energy input imparted by the mechanical mixing process. Termed specific energy input, this is defined as the energy input provided by the motor of the system divided by the feed rate and is shown mathematically in (9.3). Playing an important role in optimization and scale-up, many formulation properties are a function of a minimum specific energy input to achieve the desired results. Altering feed rate proportionally to screw speed can also allow for increases of throughput without major changes to target product properties so long as maximum peak shear does not achieve a critical threshold to drive degradation of the formulation.

$$\text{Shear Rate } \dot{\gamma} = \frac{\pi \cdot d_o \cdot n}{(d_o - d_i)}, \quad (9.1)$$

$$\text{Shear Stress : } \tau = \dot{\gamma} \times \eta, \quad (9.2)$$

$$\text{Specific Energy Input : } SE = \frac{\dot{E}}{\dot{m}}. \quad (9.3)$$

In the molten region of the process, the materials behave as viscous liquids and as a result of motion and flow restrictions pressure fields build up across the length of process section (Lim and White 1994). Pressure increases occur as a function of screw design, with mixing and kneading elements that provide minimal conveyance and having higher fill yielding greater increases. These pressure differentials provide specific function, allowing for separation and sealing of different unit operations along the length of the screw. The magnitude of pressure observed is also a function of formulation. High-melt-viscosity systems will generate larger pressures at equivalent mass flow rates to lower viscosity formulations. An example of this would be a system based on hypromellose acetate succinate where flow rates of 1 kg/h through a 2.5-mm die would result in a pressure of ~600 psi, whereas a similar system using copovidone would only yield ~200 psi when processed at

170°C. Pressure buildup also results in a localized temperature increase due to viscous dissipation which can impact product attributes of heat-sensitive materials. The resulting temperature increase due to pressure buildup can be approximated at 1°C increase for every 30 psi generated in the system.

After extrusion, material is discharged from the die and cooled using a number of different technologies. In most cases, dispersions are cooled by forced air convection to room temperature, which can be an effective technique when working with laboratory-scale processes where strand dimensions and linear velocities are relatively small. The general process may be expressed by (9.4), noting that h represents the convective heat transfer coefficient. When throughputs reach levels where convective cooling is no longer effective due to equipment geometries or product-specific cooling requirements, chill roller technology may be a viable solution. Within the chill roller, two or more rolls maintained at definable temperatures press the discharged extrudate to a film of desired thickness. This process serves to increase surface area while also providing direct contact for conductive heat transfer between solids. This is analogous to the convective situation; however, h is replaced by the conductance of the roller material (U). Generally, conductance values of roller materials are significantly greater than the coefficients provided by convective systems which utilize airflow from fans. Further improving heat transfer rates for chill roller systems are the substantially greater surface area and reduced thickness of the film when compared to the cylindrical extrudate. Additionally, greater control of temperature differentials for chill roller systems allows for superior regulation of cooling rates which can present unique advantages for post-process treatment of roll designs integrate internal flow paths for liquid temperature control which help determine the heat transfer capabilities of the system solid dispersions.

$$\text{Convective Heat Transfer Equation : } \frac{dQ}{dt} = hA(T - T_o). \quad (9.4)$$

Numerous engineering factors determine the ability to process during melt extrusion, with process parameter modifications directly impacting behavior of the system and formulation. Development of a robust design space becomes imperative and an understanding of processing ranges should be established at an early stage to justify the use of hot-melt extrusion as the production technology.

9.2.2.2 Processing Regimes for Pharmaceutical Melt Extrusion

Pharmaceutical extrusion is conducted to compound a drug substance into a larger carrier matrix to enhance product performance. In general, dispersions may be classified into three basic types of material, depending on the distribution and physical state of the active ingredient (Leuner and Dressman 2000; Serajuddin 1999; Janssens and Van den Mooter 2009). Represented schematically in Fig. 9.9, these states are crystalline solid dispersion, amorphous solid dispersion, and amorphous solid solution. Crystalline solid dispersions present multiple phases of material, which

Fig. 9.9 Schematic diagram of the different states of a solid dispersion

include a discrete crystalline phase and uniquely identifiable carrier phase. Using differential scanning calorimetry (DSC), the polymer carrier phase will be identified by a glass transition temperature while the melting endotherm of the crystalline drug substance will also be observed. Amorphous solid dispersions are systems where one or more amorphous drug-containing phases are identified. Under this definition, systems can include formulations ranging from discrete amorphous drug distributed in a carrier phase to systems where varying drug concentration gradients in the carrier manifest themselves as multiple glass transition temperatures. A specific subgroup of amorphous solid dispersions is amorphous solid solution, where the drug substance is molecularly and homogeneously dispersed within the carrier phase. In such systems, a single glass transition temperature is observed. However, one should note that the definition provided may be subject to the limitations of the quantitative methods used to assess the distribution. For example, DSC methodologies have detection limitations of approximately 30 nm (Newman et al. 2008). This allows for heterogeneity in what is perceived as an amorphous solid solution even when distributions of less than 30 nm are present. Analytical technology development in the area of dispersion characterization has received substantial attention recently and several other technologies have been applied to characterization. Techniques such as pair distribution analysis of X-ray diffraction patterns and spectroscopic assessment continue to improve resolution of drug distribution within the formulation (Newman et al. 2008; Tumuluri et al. 2008). Although nano-scale distributions are different between a dispersion (multiple T_g 's) and a solution (single T_g) and a boundary exists between the two systems, which is a function of current analytical technology, within the scope of this chapter the term amorphous solid dispersion will also include amorphous solid solution. For further discussion on detailed analytical methodologies for characterizing amorphous formulations, the reader is referred to Chap. 2.

Most pharmaceutical systems currently produced using hot-melt extrusion for bioavailability-enhancement applications are performed to create an amorphous solid dispersion. This system provides the free energy benefits of an amorphous form to increase dissolution rates and solubility while also drawing on the molecularly disperse nature of the system to maximize specific surface area at a molecular level. During manufacture of solid dispersions, material may be processed in

one of two distinct regimes based on the melting temperature of the drug substance in relation to the processing temperatures used. These regimes are the miscibility regime and the solubilization regime. While solubilization capacity of the molten polymer and miscibility of the drug substance with carrier excipients play a role in processing under both regimes, drug-substance melting temperature in comparison to processing temperature determines the dominant contribution to target product properties after manufacture. As such, operation in the solubilization regime can be defined as $T_{\text{process}} < T_m$ and the miscibility regime $T_{\text{process}} \geq T_m$.

In the miscibility regime, processing temperatures are greater than the melting point of the drug substance. Successful preparation of an amorphous solid dispersion depends on the miscibility of the drug and polymer. Systems having a solubility parameter differential of $< 7 \text{ MPa}^{1/2}$ will typically be capable of supporting a stable dispersion (Greenhalgh et al. 1999). When processing above the melting temperature of the drug substance and above the glass transition temperature of the polymer, distribution of the API in the carrier phase will be the rate-limiting step for production. Design of the screw configuration will include mixing and kneading elements to provide distributive and dispersive mixing in order to create a homogeneous dispersion. Conversely, processing in this regime for systems having a solubility parameter differential generally greater than $10 \text{ MPa}^{1/2}$ can be used for the production of bottom-up crystalline dispersions. Due to the immiscibility and anti-solvent function of the polymer phase, drug can spontaneously phase separate and recrystallize. Controlling the level of mixing and cooling rates within the system can allow for regulation of drug-particle domain size and crystal habit formed during production.

The solubilization regime which occurs when processing above the glass transition temperature of the polymer but below the melting point of the drug substance can be described by the Noyes–Whitney equation. Presented in (9.5) and used to describe drug dissolution under sink conditions, this general equation can also be applied to the analogous situation of drug dissolution in a polymer melt. Successful generation of an amorphous form will be driven by the solubility of API in the carrier materials. Thermodynamically, many drug substances have a temperature-dependent solubility in commonly used pharmaceutical polymers. At room temperature, these values are often less than 10% and dissolution does not occur on relevant timescales due to the low mobility state presented by the polymer. Raising temperatures above the glass transition temperature results in greater diffusivity (D), as described in the Stokes–Einstein equation presented in (9.6). Temperature increase also raises the equilibrium solubility of drug in the carrier (C_0). This behavior results in greater dissolution rates (dM/dt) which can be further increased by providing higher levels of shear to the system which drive a decrease in boundary layer thickness (h). Additional pre-extrusion modification of drug-substance particle size through micronization can also be an effective method to increase drug dissolution rates in the molten polymer and improve processing efficiencies by providing greater specific surface area (A) for mass transfer. Highlighting the clear inter-relation between formulation and process, successful manufacture in the solubilization regime can be

used to process high-melting-point compounds and heat-sensitive materials into amorphous forms which could not be achieved in the miscibility regime space.

Noyes – Whitney Equation Describing Dissolution Behavior (9.5)

$$\text{of Solute in Solvent : } \frac{dM}{dt} = \frac{DA}{h} (C_o - C(t)),$$

Stokes – Einstein Equation for Diffusivity : $D = \frac{k_B T}{6\pi\eta r}$. (9.6)

Manufacture of a crystalline solid dispersion is performed to reduce particle size for increased dissolution rate where the free energy benefit of an amorphous form is not required. Such a case may arise for compounds having a sufficiently low lattice energy that dissolution is not hindered by the crystalline structure or in cases where a sufficiently stable amorphous form cannot be generated. These systems may also be prepared to provide controlled release functionality to a dosage form. The top-down crystalline dispersions, particularly useful for controlled release application, are also generated in the solubilization regime; however, the goal is to find materials in which the drug has extremely limited solubility ($C_o \sim 0$). Processing conditions will also be modified to minimize temperature to lower equilibrium solubility and diffusivity, while also providing only sufficient shear to reduce particle size to the desired target product property while not imparting excess energy to substantially raise localized temperatures or significantly reduce boundary layer thickness. By careful identification of nonsolvent materials and optimization of processing conditions, it is possible to create crystalline solid dispersions using hot-melt extrusion.

9.3 Formulation Design for Melt-Extruded Dispersions

Melt-extruded solid dispersions can contain a number of different materials, each serving a specific and necessary role in the formulation. Consisting of drug substance, stabilizing polymer, plasticizer, melt solubilizer, and glidant, selection of component need and level is driven by early preformulation assessment and tuned during the formulation optimization period based on manufacturability, bioavailability, and stability of the dispersion system. Utilizing a rational design concept, a rapid prototyping approach for the development of melt-extruded solid dispersions, outlined in Fig. 9.10, can be used to identify lead compositions providing desired target properties. Within this path, property mapping and molecular modeling concepts are utilized to provide a justification for formulation selection leading to prototype development. Prototype formulations can then be rapidly screened using small-scale extrusion equipment and evaluated for manufacturability, bioavailability enhancement, and stability. This section provides a basic understanding of formulation design for melt-extruded solid dispersions while also describing the current strategies for performance assessment to support early formulation development.

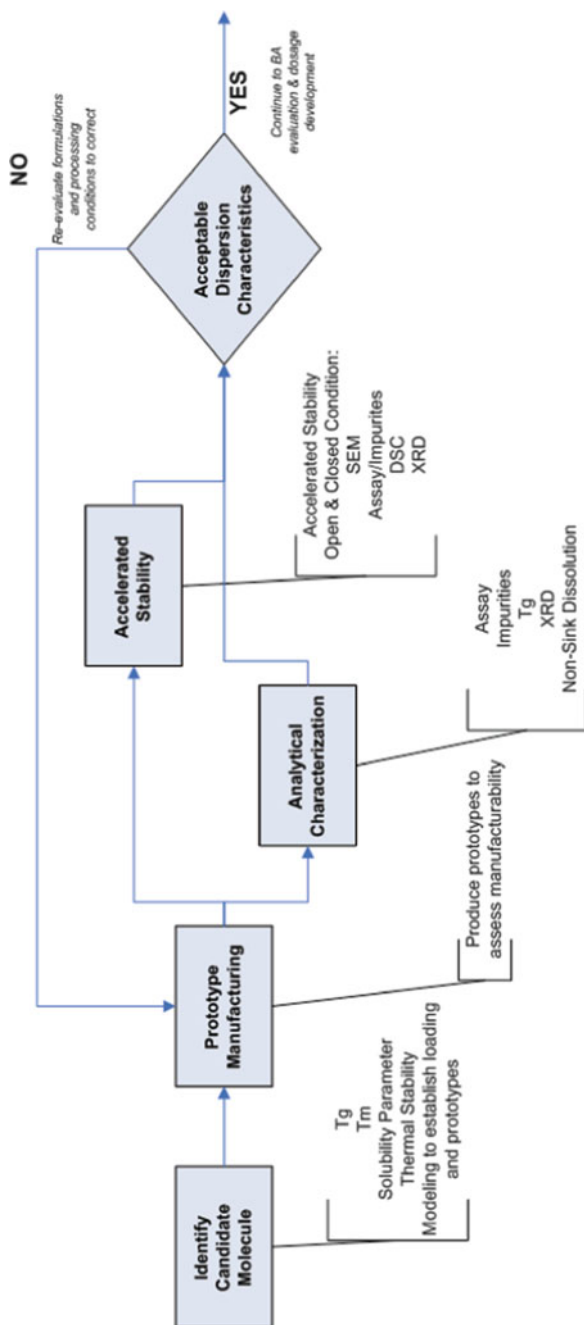

Fig. 9.10 Pathway for prototype solid dispersion development

9.3.1 *Preformulation Assessment to Support Hot-Melt Extrusion*

Solid dispersion formulation development begins with a detailed preformulation evaluation designed to identify the need for an amorphous formulation and the viability of melt extrusion as a production platform. Assessment of molecular properties, particularly around aqueous solubility, and solid-state properties allows one to identify the need for an amorphous form, with solid dispersion formulation intervention required for molecules exhibiting low aqueous solubility. Generally, if the solubility is insufficient to allow the target dose to dissolve in less than 250 ml, the compound may require solubility-enhancement technologies to achieve the desired exposure (Amidon et al. 1995). In general, many developmental compounds exhibit solubilities several fold below that, clearly delineating the need for an amorphous formulation. Compounds exhibiting slow intrinsic dissolution rates or site-specific absorption may also require solubility enhancement. Once identified as a specific need for the compound, a range of more preferred solubility-enhancement options are available, including salt formation, polymorph selection, particle-size reduction, and pH modification. Each of these options has been utilized more extensively than amorphous dispersions to improve oral bioavailability and also provide advantages of greater physical stability and production within conventional pharmaceutical unit operations. Further information on these processes is provided in various chapters of this text. In cases where these options do not provide sufficient improvements in solubility, amorphous dispersions become a viable option.

Once the need has been identified, the next step for preformulation characterization is to assess the viability of producing a stable solid dispersion. Evaluation of solubility parameters, melting point, glass transition temperature, and lipophilicity can be used to quickly assess viability. Using these values, it is possible to project the likelihood of success for an amorphous formulation. Development of basic property maps, such as that shown in Fig. 9.11, can predict the likelihood of success for the formulations by quickly identifying the maximum attainable drug loading and comparing this to the target dose estimated from the amorphous form (Friesen et al. 2008).

Physical properties of the drug substance, specifically melting point of the most stable polymorph and glass transition temperature of the amorphous form, can be used to identify the type of glass formed and the propensity for recrystallization. Current theories on polyamorphism indicate that amorphous forms may exist as a weak or strong glass which is assessed by the T_m/T_g ratio (Debenedetti and Stillinger 2001; Angell 1995, 2002). Values greater than 1.3 indicate that the material is a weak glass and will have a propensity to recrystallize on storage, while values less than 1.3 indicate a strong glass. Extrapolation of proposed solid dispersion glass transition temperature using the Gordon–Taylor equation can be used to identify appropriate materials and drug loadings capable of facilitating stable product formation while also providing an indication of required processing temperatures (DiNunzio et al. 2008). Further utilization of the Gordon–Taylor equation can be conducted to identify glass transition temperature at varying plasticizer levels to aid

Fig. 9.11 Property mapping of solid dispersions to determine maximum attainable theoretical drug loading

in processing and provide stability assessment of theoretical formulations based on the rule of 50. Originally developed by Zografi and co-workers using the Williams–Landel–Ferry equation and experimentally demonstrated using indomethacin, this model describes a solid dispersion in terms of molecular mobility as a function of glass transition temperature (Yoshioka et al. 1995; Hancock et al. 1998). Theoretically, molecular mobility increases as a function of temperature with significant mobility changes observed when the temperature is increased through the glass transition point. Zografi’s team identified a dispersion T_g 50°C greater than the storage conditions to sufficiently inhibit mobility so as to provide an acceptable product shelf life. While this rule has shown validity in many cases, there are also numerous exceptions, showing incompatibility when $T_g - T_{\text{storage}} > 50^\circ\text{C}$ and acceptable stability when $T_g - T_{\text{storage}} < 50^\circ\text{C}$. In cases where incompatibility of systems having $T_g - T_{\text{storage}} > 50^\circ\text{C}$, this is generally observed with systems having a high drug loading, a compound prone to rapid recrystallization or a system with only partial miscibility. For cases where stability is observed at differentials below the rule of 50, this is most often due to a specific intermolecular interaction which results in an elevated activation energy for recrystallization. Specific examples of such interactions include amine groups interacting with carboxylic acid groups of enteric polymers and hydrogen-bond donor groups interacting with the carbonyl acceptor group of the vinylpyrrolidone polymers.

Solubility parameters provide a measure of cohesive energy density for a material and can be used to assess the interaction potential between different formulation additives (Greenhalgh et al. 1999). The contributions of dispersive, polar, and hydrogen-bonding components of molecular structure are shown in (9.7). Differential values between components of less than 7.0 MPa^{1/2} have been correlated with

Fig. 9.12 Phase diagram of solid dispersion

miscibility while values greater than $10.0 \text{ MPa}^{1/2}$ indicated immiscibility. Applying this simple technique allows for rapid screening of candidate dispersion polymers related to the drug-substance properties. Further thermodynamic evaluation of miscibility and dispersion stability can also be assessed using adaptations of the Flory–Huggins model to generate phase diagrams of the solid dispersion at varying temperatures and compositions (Marsac et al. 2006; Zhao et al. 2011). Small-scale melting-point depression trials can also be used to accurately determine API solubility in the molten polymer as a function of temperature, allowing for identification of required processing temperatures and maximum theoretically attainable drug loading prior to prototype manufacturing. In these studies, physical mixture of drug with small fractions of polymer is prepared and analyzed by DSC to identify melting-point depression. By plotting melting-point depression, it is possible to determine the Flory–Huggins interaction parameter (χ) and develop bimodal and spinodal curves delineating the two-phase region from the homogeneous single-phase region. From such phase diagrams, as presented in Fig. 9.12, one can identify the required processing temperatures and estimate appropriate quench rates required for the development of stable or meta-stable solid dispersions.

$$\text{Solubility Parameter Equation : } \delta_T^2 = \delta_d^2 + \delta_p^2 + \delta_h^2. \quad (9.7)$$

Beyond formulation selection to achieve a stable and orally bioavailable formulation, processability of a melt-extruded system is highly dependent on the formulation characteristics. Melt viscosity plays an instrumental role in determining the motor load and pressure during manufacture (Schilling et al. 2007). Viscosity of the system is also critical for processes operated in the solubilization regime where lower melt viscosities increase diffusivity and dissolution rate of the solid drug particles in the molten polymer. By incorporating plasticizers and surfactants into

the system, processing temperatures may be lowered to improve thermal stability of the system and also aid in the manufacture of solid dispersions with high-melting-point compounds. These beneficial aspects of processing are often counteracted by a limitation to physical stability. Incorporation of these additives has been shown to compromise physical stability of amorphous forms, resulting in recrystallization on storage.

A number of polymeric materials are currently utilized for the production of melt-extruded solid dispersions and include nonionic and ionic polymers. In most cases, these materials were designed for other pharmaceutical technologies and have been applied to melt extrusion, including enteric polymers, which are commonly used for coatings, and binders, which are commonly used for granulations and compression. While these materials have shown sufficient applicability, new materials specifically designed for melt extrusion are in development and have recently begun to reach the market as well. By being specifically designed for melt extrusion, these materials will provide benefits for processing and bioavailability enhancement. A summary of materials commonly used for hot-melt extrusion to support bioavailability enhancement is provided in Table 9.2.

Utilizing basic information gathered from drug-substance characterization, it is possible to identify potential solid dispersion materials appropriate for use in development. Understanding polymer properties coupled with thermodynamic modeling of dispersion properties as a function of temperature and drug loading will provide a basis for selection of early prototype formulations. In this manner, one can significantly reduce the time required in subsequent development to arrive at the optimum dispersion while also conserving valuable drug substance.

9.3.2 Assessing Formulation Performance During Early Development

Following identification of appropriate materials and target prototype formulation as part of the preformulation exercises, small-scale dispersions will need to be manufactured to assess three critical performance areas: manufacturability, bioavailability, and stability. While generalizations of solid dispersion performance with respect to bioavailability and stability can be inferred from the behavior of systems prepared using other methodologies, some variations of physical properties may exist. Additionally, no small-scale method is capable of providing the manufacturing performance assessment seen during hot-melt extrusion. This requires the use of small-scale extruders to process materials, and the miniaturization of the process has seen significant development to support pharmaceutical development. Currently, systems as small as 7 mm can provide accurate assessments of manufacturing performance, allowing for batch sizes of less than 10 g of material. This provides an accurate and representative platform for the evaluation of formulation performance while conserving a limited early-stage drug supply. Additionally, miniaturization and advancement of analytical methodologies allow for small batch sizes to provide useful information about solid dispersion stability and bioavailability.

Table 9.2 Commonly used polymers for hot-melt extrusion

| Polymer | T_g (°C) | Grades | Notes |
|--|------------|--|---|
| Hypromellose | 170–180 | Methocel® E5 | <ul style="list-style-type: none"> • Non-thermoplastic • API must plasticize • Excellent nucleation inhibition • Difficult to mill |
| Vinylpyrrolidone | 168 | Povidone® K30 | <ul style="list-style-type: none"> • API must plasticize • Potential for H-bonding • Hygroscopic • Residual Peroxides • Easily milled |
| Vinylpyrrolidone-Vinylacetate Copolymer | 106 | Kollidon® VA 64 | <ul style="list-style-type: none"> • Easily processed by melt extrusion • No API plasticization required • More hydrophobic than vinylpyrrolidone • Processed around 130°C |
| Polyethylene glycol, vinyl acetate, vinyl caprolactam graft co-polymer | 70 | Soluplus® | <ul style="list-style-type: none"> • Newest excipient for melt extruded dispersions • Easily process by melt extrusion • Low T_g can limit stability • Not of compendial status • Stable up to 180°C |
| Polymethacrylates | 130 | Eudragit® L100-55 Eudragit® L100 | <ul style="list-style-type: none"> • Not easily extruded without plasticizer • Degradation onset is 155°C • Ionic polymer soluble above pH 5.5 |
| Hypromellose Acetate Succinate | 120 – 135 | AQOAT® - L AQOAT® - M AQOAT® - H | <ul style="list-style-type: none"> • Easily extruded without plasticizer • Process temperatures >140°C • Ionic polymer soluble above pH 5.5 depending on grade • Excellent concentration enhancing polymer • Stable to 190°C depending on processing conditions |
| Amino methacrylate copolymer | 56 | Eudragit® E PO | <ul style="list-style-type: none"> • Processing at ~100°C • Degradation onset is >200°C • Low T_g can limit stability |

9.3.2.1 Manufacturability

Instrumentation used to control the melt-extrusion process also provides significant insight into the performance of the formulation. Key measurements of torque, temperature, and pressure provide information on material flow behavior within the process section. Torque values are an indicator of the amount of energy that is being imparted into the materials being processed. Formulations exhibiting increased levels may have high melt viscosities and require the addition of a plasticizer. Similarly,

one can also identify if an excessive number of mixing sections are present on the extruder, leading to elevated torque levels. Elevated melt pressure and temperature may also provide information about formulation flow while also identifying if die bore cross-sectional area is insufficient for the flow rates used in manufacture. Representative information about manufacturing performance can also begin to be characterized, which will serve as a basis for later-stage scale-up evaluation. Determination of specific energy input and screw design required to achieve target product properties establishes the beginnings of an operational design space. Similarly, temperature profiles developed at the early stage are translated to larger geometrically similar equipment as development progresses.

Assessment of solid dispersion amorphous nature is conducted using at-line evaluations and traditional analytical characterization methods. During production, amorphous systems frequently form transparent glasses, similar to that shown in Fig. 9.13, which allows for easy identification of residual crystallinity and provides a first-line assessment of product attributes. Polarized light microscopy is an excellent qualitative technique which can support at-line determination of the properties. Further confirmation of amorphous nature is achieved through the use of powder X-ray diffraction, DSC, and Fourier transform infrared spectroscopy where characteristic markers associated with the crystalline form can be detected. While these techniques have general detection limits of ~2–5% crystalline material, method development and optimization can be used to refine these and other technologies to detection levels of residual crystallinity to less than 0.1% w/w (Newman et al. 2008). An understanding of phase distribution within the dispersion is also achieved with modulated differential scanning calorimetry (mDSC), where homogeneity is denoted by a single glass transition temperature. Notably, a crystalline dispersion will contain both a glass transition temperature associated with the polymer phase and melting endotherm of the drug substance. This type of dispersion will also be visually opaque at line, allowing for clear identification of amorphous and crystalline forms. Similarly, immiscibility of formulation additives can result in opacity of the system that will also manifest itself in detectable multiple phases by mDSC. In extreme cases of immiscibility, visual observations of phase separation may occur at line where phases of different viscosity are observed to exit the die region.

9.3.2.2 Stability

Stability evaluation of melt-extruded solid dispersions is conducted in a similar fashion to other types of solid dispersions by placing materials under aggressive storage conditions (elevated temperature and humidity) to induce stress on the system. They are then evaluated using a battery of qualitative and quantitative techniques. From a regulatory perspective, the most aggressive condition the material will see during shelf life is storage at 40°C and 75% relative humidity. For rapid stability assessment, it is recommended to store dispersions at these conditions in an open manner to allow the system to reach moisture equilibrium with the environment. Since moisture is a potent plasticizer, allowing the system to reach moisture

Fig. 9.13 Images of amorphous extrudate

equilibrium with the environment presents a worst-case scenario for storage. Further increases of temperature and humidity can provide greater stress on the material but may not be representative of the final storage conditions.

Samples can then be evaluated for chemical and physical stability. Chemical stability of the dispersion can be performed using conventional analytical techniques such as high-performance liquid chromatography, with the specific method highly dependent on the properties of the drug substance. Physical stability is assessed by a combination of qualitative and quantitative methods aimed at identifying recrystallization. Commonly used techniques include those mentioned above for initial quality evaluation along with qualitative methods such as polarized light microscopy (PLM) and scanning electron microscopy (SEM) to visually identify the presence of crystalline materials (Bruce et al. 2007). Owing to increased entropic freedom at the surface, molecular mobility at the interfacial regions is greater than that in the bulk, facilitating recrystallization on the exterior of solid dispersion particles (Zhu et al. 2008; Qian et al. 2010). Exposure to elevated moisture and temperature helps to plasticize the interface and further increase molecular mobility, allowing SEM to be used for identification of recrystallization on storage. Similarly, PLM can be used to identify crystallized material in the solid dispersion particles. Both methods generally tend to be more sensitive than quantitative techniques; however, they cannot be used to identify the extent of recrystallization. Storage placement of samples under different moisture controls allows for decoupling of moisture and temperature effects responsible for recrystallization while

also providing the ability to extrapolate performance. If moisture absorption is identified as a failure mechanism associated with dispersion stability, it may be possible to limit recrystallization with moisture-resistant dosage form development or product packaging. Temperature-associated failures become more difficult to address; however, in rare cases, they could be mitigated through stringent and restrictive storage requirements for the drug product, such as maintaining the material under refrigeration.

9.3.2.3 Bioavailability

Amorphous solid dispersions prepared by hot-melt extrusion are undertaken to enable drug delivery through improved bioavailability. During development, *in vitro* characterization of performance is necessary to identify lead formulations but conventional techniques are often insufficient to describe the dissolution behavior of an amorphous form. Resulting from the amorphous nature, formulations exposed to an aqueous environment will rapidly dissolve and drive a supersaturated concentration (Brouwers et al. 2009; Alonzo et al. 2010). Nucleation and growth will begin to occur, causing precipitation which drives the system to thermodynamic equilibrium. As a result of this behavior, a number of different colloidal species will be present in solution, many of which will exist below 200 nm, thus limiting the ability of conventional analytical technologies to identify species in solution.

Within current dissolution theory of amorphous formulations, free-drug concentration is believed to be the primary contributor to oral bioavailability enhancement. Free drug is defined as individual drug molecules dissolved in solution without significant complexation to other multi-molecular aggregates. Other species present in solution include drug-polymer nano-structures, nano-aggregates, free polymer, dissolving solid dispersion, bile salt micelles, and larger precipitated aggregates. Each of these species contributes to a pseudo-equilibrium with free drug in solution, during which time free drug is absorbed while the system approaches thermodynamic equilibrium. Formulating solid dispersions requires identification of materials capable of maximizing the free-drug concentration, while, also extending the duration, elevated concentrations are maintained. Materials capable of providing such an effect are termed concentration-enhancing excipients, with the majority of these materials being ionic amphiphilic macromolecules which are ionized at intestinal pH (Friesen et al. 2008). From a functional perspective, the large molecular weight provides steric hindrance to recrystallization while the ionized state prevents aggregation and growth of particles, leading to prolonged durations of supersaturation (Friesen et al. 2008; Brouwers et al. 2009; DiNunzio et al. 2010c). The amphiphilic nature of the material allows hydrophilic groups to interact with water, while hydrophobic interactions maintain stabilization of the free drug in solution (DiNunzio et al. 2010c).

Due to the small size domain of the different species in solution and the varying degrees they contribute to bioavailability, analytical technologies used for

characterization must be capable of separating free drug from the other species. Current free-drug characterization technologies rely on passive diffusion through an isolating membrane to assess concentration levels. Dialysis methods and adaptations of the parallel artificial membrane permeability assay (PAMPA) have been successfully implemented. These techniques utilize membrane cutoffs to ensure that higher-molecular-weight material is nonpermeable into the receptor component, while low-molecular-weight drug molecules are capable of diffusing through the system. More accurate than many of the centrifuge and filtration counterparts, permeability through the membrane is used to determine free-drug concentration in the donor compartment. While diffusion techniques provide the most accurate assessment, frequently it may be acceptable to use alternate techniques as surrogates by measuring total drug in solution, which also includes many of the colloidal species. In comparison to conventional sink dissolution testing, these methods can be more reliable predictors of *in vivo* performance.

Another option for screening bioavailability enhancement of melt-extruded dispersions is the use of preclinical animal models, although physiological differences compared to man may limit predictability. These issues can become even more challenging for BCS II/IV compounds, where volumes, pH, transit times, and membrane permeability may not provide an accurate prediction of formulation performance in man. While a detailed discussion of animal models is outside the scope of this chapter, it is important to highlight the potential issues of predicting oral bioavailability of poorly soluble formulations with preclinical models. One example of this variability by species is membrane permeability. In relation to man, primate models tend to provide more similar permeabilities than canines. As a result, oral bioavailability may be overpredicted in dogs due to higher permeability. This behavior may become even more exaggerated in amorphous formulations of BCS II and IV compounds. For further information on preclinical bioavailability testing, the reader is referred to Chap. XX.

9.4 Scale-Up and Process Optimization

The development of melt-extruded formulations requires the design of compositions that facilitates processing, provides appropriate stability, and also enables the therapy by yielding greater bioavailability. Formulation additives must provide functionality to processing and solubility enhancement. Formulation development will begin with a sound preformulation screening and subsequent prototype production to identify final compositions through a combination of *in vitro* and *in vivo* screening. Further optimization ultimately leads to the selection of a final formulation that will support commercial manufacturing. This section describes the current scale-up and process optimization strategies for hot-melt-extrusion processes within the framework of quality by design (QBD).

9.4.1 Process Optimization and Scale-Up for Melt-Extrusion Processes

The initiation of process optimization is largely scale independent and driven by the properties of the system being developed. For systems showing process sensitivity, such as heat-sensitive materials, there will generally be a need for optimization at an earlier stage than that required for a more robust product. Similarly, the need and rate of scale-up will largely be driven by drug product demand to support clinical trials, noting that the continuous nature of extrusion does not provide a batch size limitation but rather a product throughput limitation. While the author has provided several other references for detailed melt-extrusion optimization and scale-up procedures (Steiner 2003; Schenck 2010; Todd 1995; Dreiblatt 2003), this section summarizes the key aspects of the development for pharmaceutical applications.

Early-stage process optimization will be conducted either to address issues with drug product attributes or to improve production efficiencies. During this time, key-controlled process-independent variables of barrel temperature, feed rate, screw speed, and screw design will be modulated to assess the impact to target product attributes. Since these variables represent underlying dependent properties of the system which are key to functionality of the process, such as melt viscosity, fill, and shear rate, significant interactions may be observed requiring a knowledge-based approach to development and the use of a statistical design of experiments to better elucidate the operational space which is represented schematically in Fig. 9.14. Factorial designs capable of being expanded to response surface studies can provide a sound methodology for identifying primary control variables as well as optimizing their responses around minimization of impurities and maximization of feed rate. During this stage, drug product attributes related to both the drug substance and the carrier materials will be evaluated. Changes to production properties have been demonstrated to have a substantial effect on excipient properties as well. One also notes that residence time is coupled with feed rate which will drive a general reduction of chemical impurities as throughput increases. For amorphous dispersions produced in the solubilization regime, the reduction of residence time may be brought to a critical point where residual crystalline material exceeds the allowable limits of the process or the homogeneity of the dispersion is not achieved. For systems developed in the miscibility regime, they will primarily suffer from distribution limitations. This illustrates the critical balance that must be achieved during optimization to achieve design product rates and product properties. When production rates cannot be maximized to the desired throughputs while yielding the required product attributes, scale-up will be triggered to support continued development.

Basic scale-up of the extrusion process is achieved using geometrically similar extruder designs between scales while observing several key scale factors associated with throughput and specific energy input. Geometric similarity is achieved by providing the same number of divisions per kilogram of material to ensure represen-

Fig. 9.14 Representative diagram of design space for hot-melt extrusion

tative distributive mixing while also maintaining the shear stress rate per kilogram of material to match the dispersive properties of the system. Transitioning from a smaller unit to a larger unit results in an increase in system free volume where it will be desired to maintain the same scale-independent parameter of fill. As such, mass flow rates within the system will scale as the cube of the diameter ratio of the extruder, shown in (9.8). Maintenance of specific mechanical energy between scales will yield comparable dispersions between scales, provided geometrical similarity of the equipment is maintained. Further optimization of the process upon scale-up can be achieved by increasing feed rate and screw speed proportionally to maintain specific energy input, although care must be taken to ensure that peak shear rates at higher screw speeds do not adversely impact product attributes.

$$\text{Mass Flow Rate Scale – up Factor for Hot Melt Extrusion: } m_2 = m_1 \left(\frac{d_2}{d_1} \right)^3. \quad (9.8)$$

In support of early development, basic process optimization around key controllable independent process variables can be used to deliver target product properties of the solid dispersion. Balancing throughput and energy input considerations can be used to provide a knowledge-based approach to development, while a DOE-based approach can yield greater information about the interaction of process parameters. Furthermore, scale changes can be accommodated using a series of

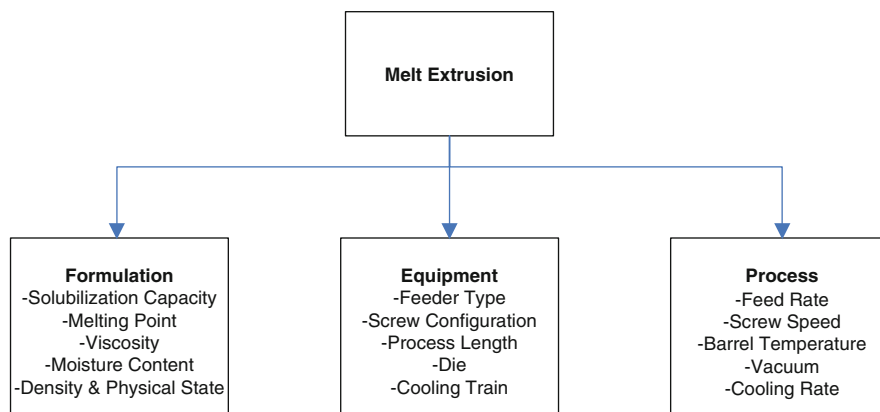

Fig. 9.15 Diagram of melt-extrusion-process properties

relatively simple principles, provided geometric similarity is maintained. While these rules will help to work within the design space, they do not ensure a fully optimized production process, which can only be achieved through the implementation of a more rigorous QBD approach, implementing process analytical technology (PAT).

9.4.2 QBD and PAT for Melt-Extrusion Processes

Early development approaches provide useful fundamental strategies for addressing process limitations; however, the complex interaction of dependent properties which govern the extrusion process requires very rigorous approaches to fully optimize the manufacturing processing to maximize the production value. Examination of the process shows that a number of factors contribute to the final product attributes, each of which requires in-depth consideration and unique approaches to assessing their impact. Represented schematically in Fig. 9.15, these properties can be classified into three general types (formulation, equipment, and process) which contribute to the behavior of key dependent variables within the system. For successful optimization, the ability to decouple and describe key process-dependent variables from the process independent controls to accurately describe behavior of the system. The complexity of the task and the amount of data generated during such an undertaking also make the application of PAT a necessity to support the optimization. Application of in-line PAT technology allows for accurate real-time monitoring of chemical compositions which can be provided by multiple independent feed streams. Real-time oscillations associated with system perturbations can be accurately monitored and modeled to ensure that sufficient dampening is provided by the system to account for natural process variations. Step change modifications to feed rates of different

components can be used to identify process response factors, while pulsed component inputs can be used to determine residence time distributions. Computational and mathematical modeling of the system based on reaction kinetics models of CSTRs and PFRs can then be used to interpolate performance within the ranges of the studied design space. Continued application of PAT to routine product also assists in the identification and isolation of out-of-specification material, which results from unanticipated system perturbations. In the future, this may also lead to the real-time release of material from in-line measurements during production. For a more comprehensive review of applications of QBD and PAT to melt-extrusion process development, the reader is referred to *Achieving a Hot Melt Extrusion Design Space for the Production of Solid Solution in Chemical Engineering in the Pharmaceutical Industry: R&D to Manufacturing*.

9.5 Case Studies

Many drug discovery pipelines contain a majority of compounds with limited solubility that require formulation intervention to improve delivery. Over the last decade, many new products have been developed utilizing solid dispersion technology to improve bioavailability. This section details several of the most recent developmental and marketed products using hot-melt extrusion to enable therapeutic performance.

9.5.1 Anti-viral Therapies

Human immunodeficiency virus, first discovered in 1981, affects nearly 0.6% of the world's population. Particularly dangerous in the Third World, global efforts to develop new therapies have been undertaken by a number of major pharmaceutical companies and led to the discovery of multiple drug products which have transitioned the disease from a death sentence to a more manageable condition. Many drug products within this class are formulated as drug cocktails containing multiple compounds to reduce viral load by targeting multiple different mechanisms of replication and survival. As these drugs continued to develop, many of the new therapies are classified as BCS IV compounds due to extensive metabolism and poor aqueous solubility. When addressing oral bioavailability limitations for BCS IV molecules, intervention must address both limiting aspects. One common approach to addressing metabolic conversion of the target moiety is the inclusion of a secondary component to inhibit or saturate conversion pathways in vivo. This strategy, commonly referred to as a "booster," is best exemplified in Kaletra[®] which delivers improved lopinavir levels with the incorporation of ritonavir as a booster to inhibit metabolic activity (Breitenbach 2006). Both Norvir[®] and Kaletra[®] present

excellent examples of applying melt-extrusion technology to develop formulations and improve the overall therapeutic efficacy of the product.

Ritonavir was discovered by Abbott Laboratories in the late 1980s as part of a federally funded initiative to develop HIV/AIDS therapies. Exhibiting low aqueous solubility, two polymorphic forms of the compound were identified. Form II was the higher-energy form and provided a solubility benefit and also presented a potential for conversion to the lower-energy form over time. Norvir[®] was originally developed as a liquid-filled capsule formulation containing ritonavir form II. The product received approval and was marketed for a short period of time before form conversion of the unstable drug substance was observed (Bauer et al. 2001). Due to the conversion, bioavailability of the product was reduced which required a product recall and ultimate reformulation. This reformulation was achieved through the use of hot-melt extrusion to prepare an amorphous solid dispersion. Utilizing the Soliq's Meltrex formulation technology, an amorphous solid dispersion of ritonavir in a matrix of Kollidon[®] VA 64 and surfactants was designed (Breitenbach 2006). Specifically engineered to prevent recrystallization, ritonavir drug loading is minimized to the solubility of the amorphous form in the matrix. Additionally, the release mechanism is an extended type which presents the drug as a nanoparticle dispersion capable of maintaining supersaturation and increasing oral bioavailability. Through the use of this technology, issues of form conversion have been eliminated while also providing patients with a more robust dosage form which does not require refrigeration to maintain stability.

A similar example is also observed with Kaletra[®], a combination product containing lopinavir and ritonavir. Similar to Norvir[®], first-generation Kaletra[®] was formulated as a soft-gelatin capsule which required frequent multiple-unit administration and refrigerated storage to maintain stability. Through the application of Meltrex[®] technology, Abbott Laboratories was able to reduce the pill burden while also eliminating the need for refrigerated storage. Championed as a breakthrough dosage form, Kaletra[®] currently represents the most successful melt-extruded dosage form to address solubility limitations.

In the design of these systems, several technological limitations needed to be addressed. Following the failure and ultimate product recall around the Norvir[®] soft-gelatin capsule product, stability of the dosage form was critical. Applying fundamental solid-state characterization principles described earlier, the thermodynamic solubility of both drug substances in the matrices was identified. This facilitated the development of dispersions with drug loadings of 2 and ~4 percent for lopinavir and ritonavir, respectively (Kessler et al. 2009). Additionally, ritonavir exhibited heat sensitivity which challenged dispersion production by melt extrusion. Applying patented screw elements and designs shown in Fig. 9.16 to minimize localized temperature buildup and residence time, it was possible to reduce impurities by 0.2% (Kessler et al. 2009). Through careful consideration of the solid-state properties, engineering aspects of melt processing, and also bioavailability considerations, it was possible to design solid oral dosage forms capable of providing the benefits of soft-gelatin capsule systems with improved stability aspects and size properties to enhance patient compliance.

Fig. 9.16 Novel screw designs for production of kalectra[®] solid dispersions

9.5.2 Anti-Fungal Medications

A number of azole antifungal compounds exhibit poor solubility, including ketoconazole, itraconazole, and posaconazole. These weak bases exhibit a pH-dependent solubility presenting a further challenge to design a highly bioavailable drug product. While conventional technologies have been applied to ketoconazole drug products with sufficient exposure levels, itraconazole became one of the first commercially marketed amorphous solid dispersions to enhance oral bioavailability. Marketed as Sporanox[®], the dispersion is prepared by an organic solvent drug layering process of itraconazole and hypromellose onto sugar spheres (Gilis et al. 1997). The material is then surface coated with a protective layer of polyethylene glycol, dried, and metered into gelatin capsules to provide a finished dosage form. Although able to provide improved oral bioavailability, the product still exhibited variable absorption and substantial food effect which was particularly apparent in the presence of acidic beverages such as cola (Jaruratanasirikul and Kleepkaew 1997). Numerous attempts to improve oral bioavailability were made through the production of a variety of manufactured systems, including melt-extruded dispersions. Attempts using hot-melt extrusion to prepare nonionic solid dispersions with materials such as Kollidon[®] VA 64 and Eudragit[®] E PO were successful at rendering an amorphous form; however, they failed to provide substantial bioavailability, although dissolution testing suggested a potential to improve performance (Six et al. 2002, 2004, 2005). Subsequent studies by Miller et al. clearly demonstrated that the most effective delivery strategy for the weakly basic compound was to target release at the upper small intestine through the production of enteric solid dispersions (Miller et al. 2008a, 2008b). In these trials and summarized in Table 9.3, significant increases in AUC and C_{max} were reported for enteric dispersions when compared to conventional nonionic formulations in rat models.

Effectiveness of enteric solid dispersions derives their performance through two major mechanisms. First, these dispersions dissolve at pH values greater than 5.0 depending on the material selected. This triggers dissolution and supersaturation at the upper small intestine, which is the primary site of absorption for many

Table 9.3 Bioavailability of nonionic and enteric itraconazole solid dispersions

| Formulation | C _{max} (ng/ml) | T _{max} (h) | AUC (ng·h/ml) |
|-----------------------|--------------------------|----------------------|----------------|
| Methocel™ E50 | 732 ± 187 | 4.9 ± 2.2 | 6,195 ± 1,134 |
| Eudragit® L100-55 | 630 ± 695 | 9.9 ± 9.7 | 7,335 ± 10,224 |
| 20% Carbopol Additive | 1,198 ± 584 | 4.4 ± 1.6 | 11,107 ± 3,579 |
| 40% Carbopol Additive | 663 ± 186 | 5.6 ± 0.5 | 5,830 ± 1,943 |

pharmaceutical compounds. This allows the formulation to avoid premature gastric supersaturation and precipitation which may limit bioavailability benefits of solid dispersions. The second major benefit for these materials is derived from the partially ionized nature of the polymer. After dissolution, stabilization of supersaturated is mediated through drug–polymer interactions (Warren et al. 2010; Brouwers et al. 2009). Although not particularly well understood, a number of studies have attributed this behavior to a combination of steric hindrance and hydrophobic interactions. Due to the partial ionization of the polymer in solution, growth rates of drug–polymer aggregates in solution are slowed and allow polymers such as cellulose acetate phthalate and hypromellose acetate succinate to provide greater stabilization efficiency.

Posaconazole, structurally similar to itraconazole, is also a weakly basic triazole antifungal that exhibits pH-dependent solubility. Without intervention, the drug dissolves in the acidic conditions but rapidly precipitates in the environment of the upper small intestine to levels below 1 mg. Using a conventional suspension formulation and commercially marketed as Noxafil®, the formulation exhibits highly variable bioavailability with a substantial food effect. Applying concepts similar to the aforementioned itraconazole strategies, a novel posaconazole drug product is under development by Merck using hot-melt extrusion (Fang et al. 2009). Preparing solid dispersions of posaconazole with hypromellose acetate succinate (HPMCAS) Merck scientists have developed a product capable of providing significantly improved oral bioavailability while addressing issues with heat sensitivity of the drug substance. Posaconazole exhibits significant degradation at temperatures above 160°C. By designing a formulation where the molten polymer solubilizes posaconazole below the melting point. This eutectic behavior allows for production at reduced temperatures to improve the stability of the drug substance. Manufacturing of the extrudate is conducted using a pre-blending process to admix posaconazole with HPMCAS-M and direct gravimetric feeding into a twin-screw co-rotating extruder. The material is collected and cooled before milling to a particle size range of 75–300 µm. Milled extrudate is then combined with extra-granular materials and prepared as a tablet or capsule containing a 100-mg dose.

Nonsink dissolution testing of formulation using a pH change methodology highlighted the enteric protection of the formulation. Shown in Fig. 9.17, limited dissolution occurred in the acidic environment representative of the stomach. Following pH change, substantial dissolution and supersaturation of the formulation occur which provide more efficient targeting to the upper small intestine.

Fig. 9.17 Posaconazole in vitro release and oral bioavailability. Adapted from Fang et al. 2009

The concentration-enhancing behavior of the enteric polymer also helps to prevent precipitation for reduced variability. As part of drug product development, extrudate tablet and capsule formulations were compared to Noxafil® at a 100-mg dose in a crossover study in healthy volunteers examining fed-state and fasted-state plasma profiles. Presented in Fig. 9.17, these results showed substantial oral bioavailability improvements with reduced food effect. Patient-to-patient variability was also substantially reduced, allowing for improved target product attributes of the formulation.

9.5.3 Cholesteryl Ester Transfer Protein Inhibitors

Cardiovascular vascular disease currently represents one of the largest treatment areas by revenue, with numerous blockbusters such as LDL-lowering products such as Lipitor. One series of next-generation cardiovascular compounds known as cholesterol ester transfer protein inhibitors aims to increase HDL levels and reduce heart disease. Given the financial potential of these compounds, representing a market potential of over \$10 billion, numerous major pharmaceutical companies have maintained active programs to develop these compounds. Most notably, Pfizer, Merck, and Hoffmann-La Roche all have reported data for formulations of these compounds and their use in preclinical and clinical trials.

Torcetrapib, developed by Pfizer, was a poorly soluble compound that required the utilization of spray-dried dispersion technology to improve oral bioavailability. Formulations of torcetrapib solid dispersions were prepared with a number of

concentration-enhancing polymers, including cellulose acetate phthalate (CAP) and hypromellose acetate succinate (HPMCAS) which have been described throughout several patents (Friesen et al. 2004). Drug product study designs clearly demonstrated the applicability of HPMCAS for improving exposure and was used as the primary polymer for the amorphous clinical formulations. Intended for use in a combination product with atorvastatin (Lipitor) to extend the franchise, the program was progressed to phase III. In the long-term ILLUMINATE clinical trial, adverse events including increased heart failure and increased rates of angina were observed at a greater rate in the torcetrapib and atorvastatin group than the control group consisting of atorvastatin alone (Tall et al. 2007). While sufficient exposures were observed through formulation enablement by amorphous formulation intervention, these adverse events ultimately led to the termination of the program. Even with the failure of torcetrapib, continued development of the CETP target has continued. These compounds, such as torcetrapib, exhibit poor aqueous solubility and have been developed using unique formulation strategies applying hot-melt extrusion.

In the case of a Hoffmann-La Roche compound, the drug substance exhibits low solubility and is also subject to extensive degradation and metabolism. Traditional formulation and manufacturing of an amorphous formulation are not possible as a result of chemical instability of the amorphous form in the solid state. In order to improve dissolution rate of the composition, a novel in-situ bottom-up microcrystallization process was developed (Miller et al. 2011). Across the length of the screw two distinct process sections were defined, specifically a solubilization zone and a recrystallization zone. As material is fed into the extruder, melt processing of the drug substance occurs, allowing for molecular level dispersion of the drug in the carrier phase. After transiting to the recrystallization zone, material is quenched under agitation to reduce drug solubility in the carrier and result in recrystallization. Due to immiscibility of the drug in the carrier phase at low temperatures, phase separation and recrystallization occur and through careful regulation of the internal mixing conditions it is possible to regulate the size of recrystallized particles. Using a formulation of API and Eudragit® E PO, the inventors were able to demonstrate particle-size reductions compared to micronized API while significantly improving dissolution rate due to the intimate mixture of drug with acid-soluble polymer. Representative processing is shown in Fig. 9.18. Further examples also illustrated the application of in-situ crystallization to formulations of poloxamer and isomalt, illustrating the utility of the technology to support high drug loading and demonstrating that elevated loading contributed to larger particle size on recrystallization, which ultimately yielded reductions in dissolution rate. Most importantly, the formation of a crystalline drug-substance phase provided the required drug product stability, both physical stability against recrystallization and chemical stability against decomposition. This allowed for successful manufacture of rapidly dissolving tablet drug products.

Anacetrapib is another CETP inhibitor being developed by Merck with poor aqueous solubility that requires a solid dispersion formulation to achieve the required oral bioavailability. Developmental formulations were prepared using spray drying and hot-melt extrusion (Geers et al. 2010). Hot-melt-extruded formulations were

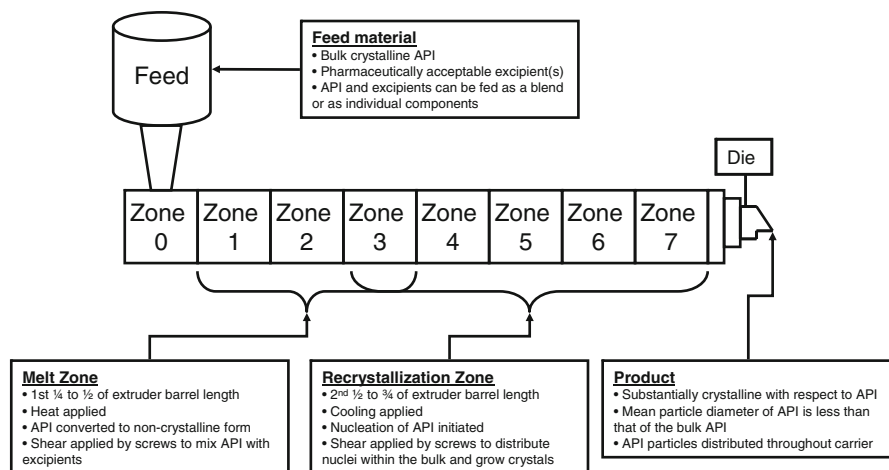

Fig. 9.18 In-situ recrystallization process design using hot-melt extrusion

prepared using a Kollidon® VA 64 matrix with additional surfactant materials at levels up to 15%. Dosage forms containing granules prepared by hot-melt extrusion were evaluated in preclinical trials using Rhesus monkeys with a comparison to crystalline drug-substance formulations and spray-dried dispersion formulations made with HPMCAS. Summary data from the preclinical evaluations are provided in Table 9.4. Hot-melt-extruded solid dispersions using Kollidon® VA 64 and vitamin E TPGS provided superior bioavailability and reduced variability compared to the spray-dried dispersion product, while increasing oral bioavailability by almost threefold when compared to the crystalline formulation. Currently continuing clinical development, positive results have been reported to date and the program is expected to continue, relying on the ability of melt extrusion to enable drug product performance.

9.5.4 Shaped Delivery

Hot-melt extrusion currently serves as an ideal technology to produce amorphous solid dispersions, providing increased dissolution rates and greater solubility through manipulation of the thermodynamic properties of the system. In certain cases systems may not be suitable for amorphous formulation due to physical or chemical instability. In the case of many new developmental compounds, limited aqueous solubility is only one hurdle which must be addressed to develop a functional drug product. Product efficacy is derived from both efficacy and distribution. For many compounds, particularly potent oncology and immunosuppressant therapies, the desired distribution is only to the localized area of therapy and not to systemic circulation where increased side effects may be observed. Numerous attempts

Table 9.4 Preclinical oral bioavailability of anacetrapib solid dispersions

| AUC_{0-24} (mM-h) | 0.67±0.032 | 1.99±1.10 | 2.29±0.21 |

to provide the necessary targeting have been researched; however, novel device manufacturing has been shown to be the most commercially viable mode. Several key examples, including NuvaRing® (De Graaff et al. 2007) and Zoladex® (Breitenbach 2002), have used hot-melt extrusion to produce devices capable of providing prolonged delivery of challenging compounds.

In the case of NuvaRing®, an ethylene-vinyl acetate depot system was developed to provide controlled vaginal release of progesterone and estrogen over a 21-day period as an alternative to once-daily orally administered contraceptives. Manufacturing consisted of co-axial extrusion of an inner core of ethylene-vinyl acetate containing drug and an external ethylene-vinyl acetate layer having approximately 300- μ m thickness to regulate drug release via diffusion through the external membrane. Following extrusion, the product is cut to length and bonded to create a ring-shaped device. The precision technologies utilized in the external membrane product which support NuvaRing® were originally developed to support numerous applications for parts manufacture almost half a century ago and serve to illustrate how hot-melt extrusion can be used to provide well-controlled target product properties on scales not previously seen in pharmaceutical production.

Requiring similar fine product control, Zoladex® is an injectable controlled release implant manufactured from poly (lactic-co-glycolic acid) that provides sustained release of goserelin acetate for the treatment of advanced prostate cancer. Administered subcutaneously through a 16-gauge needle, the drug product manufacturing process draws on the control provided by melt extrusion to deliver a geometrically precise product. Small-diameter extrusion and draw-down technologies which support the manufacture of Zoladex® were adapted from medical device fields where the production of fine bore tubing is common. Additionally, terminal sterilization by gamma irradiation provides a product that can be administered to improve bioavailability of the drug product while also reducing dosing frequency. Patient compliance with the product is also greatly increased by the biodegradable nature of the system, which is converted to lactic acid and glycolic acid *in vivo*.

“Hot” off the presses of regulatory approval, Ozurdex® is the newest melt-extruded product to reach the commercial market and is an implantable device containing dexamethasone in a PLGA carrier matrix (EMEA Editor). Used in the treatment of macular edema following either branch retinal vein occlusion or central retinal vein occlusion, the drug product is administered as an intravitreal injection that provides prolonged delivery. Unlike conventional dexamethasone injections

which have a half-life of 3 h and topical administrations where almost no drug reaches the posterior segment, the biodegradable device provides controlled release for a 6-month period. Representing the current state of the art for production, geometry, and drug–device synergy, this product truly enabled therapy of a poorly soluble compound.

During compounding using hot-melt extrusion, dexamethasone intimately mixes with ester and acid-terminated PLGA to provide the desired mechanical properties, stability behavior, and dissolution performance. Processed at temperatures less than 150°C, the drug is maintained in the device as an intimate crystalline dispersion within the carrier matrix where it is shaped through a pulling and cutting process to form a cylindrical drug product (460 μm \times 6 mm) (EMEA [Editor](#); Shiah et al. 2008). During design of the drug product, careful attention to geometry was given in order to provide a system capable of delivery with a 22-gauge needle while also providing minimal cross-sectional area to ensure a self-sealing wound following removal of the needle. Data from preclinical trials in rabbits, shown in Table 9.5, illustrated that above a critical diameter, which was also dependent on application technique, wound size became such that additional sutures were needed (Weber et al. [Editor](#)). For a commercial product, additional post-injection surgery to close the injection site would reduce patient compliance, rendering the product ineffective.

Studies also illustrated the importance of administration technique and therefore device on the overall performance of the product. The drug product device consists of an externally silicone oil-lubricated 22-gauge hypodermic needle with a lever to trigger single-use injection. Prevention of air entrainment upon injection is achieved through the engineering of extremely small clearances between the drug product cylinder and the needle walls. A representative image of the injection mechanism is illustrated in Fig. 9.19. Device assembly and loading are conducted using automated vision systems which provide accurate and reproducible production. The system, drug product, and device are then terminally sterilized using gamma irradiation (25–40 kGy) to yield a final drug product. Although the sterilization process does result in chain scission which lowers molecular weight, no significant changes to drug release rate have been observed as a result. Ultimately, the cumulative product of extrusion and device provides a synergistic performance benefit, helping to deliver therapy of a compound that could not be achieved using conventional means.

9.6 Summary

Over the last quarter century, tremendous transition has been observed in the pharmaceutical industry resulting from technological advancements yielding more compounds with less solubility, a need for innovative and integrated drug products to provide true intellectual property protection while also experiencing global austerity to drive the implementation of cost-effective manufacturing platforms. Fortunately, melt extrusion has emerged as an innovative solution within the

industry that is supplemented by over a century of technological achievements in other theaters. While perceived by many to be a recent development for pharmaceuticals, the first marketed melt-extruded drug product using melt extrusion reached the market in 1981 with subsequent products developed periodically over the last thirty years. As summarized in Table 9.6, the number of programs publically disclosed have increased substantially as a result of the different industry pressures

Table 9.6 Currently marketed and developed drug products using hot-melt extrusion

| Product | Indication | HME purpose | Company | Approval stage |
|--|------------------------|---------------------------------|------------------------|---|
| Lacrisert (HPC Rod) | Dry eye syndrome | Shaped system | Merck | Marketed |
| Zoladex (Goserelin Acetate Implant) | Prostate cancer | Shaped system | AstraZeneca | Marketed |
| Implanon(Etonogestrel) | Contraceptive | Shaped system | Organon | Marketed |
| Gris-PEG (Griseofulvin) | Anti-fungal | Crystalline dispersion | Pedinol pharmaceutical | Marketed |
| Rezulin (Troglitazone) | Diabetes | Amorphous dispersion | Wyeth | Withdrawn due to API associated toxicity |
| PalladoneTM (Hydromorphone) | Pain | Controlled release | Purdue pharma | Withdrawn due to alcohol related dose dumping |
| NuvaRing® (Etonogestrel, Ethinyl Estradiol) | Contraceptive | Shaped system | Merck | Marketed |
| Norvir® (Ritonavir) | Anti-viral (HIV) | Amorphous dispersion | Abbott laboratories | Marketed |
| Kaletra® (Ritonavir/Lopinavir) | Anti-viral (HIV) | Amorphous dispersion | Abbott laboratories | Marketed |
| Eucreas® (Vildagliptin/Metformin HCl) | Diabetes | Melt granulation | Novartis | Marketed |
| Zithromax® (Azithromycin) | Anti-biotic | Melt congeal (Taste masking) | Pfizer | Marketed |
| Orzudex® (Dexamethasone) | Macular edema | Shaped system | Allergan | Marketed |
| Posaconazole | Anti-fungal | Amorphous dispersions | Merck | Development |
| Anancetrapiib | Cardiovascular disease | Amorphous dispersion | Merck | Development |
| Dapivirine, Maraviroc, BMS793, CMPD167 | Anti-viral | Shaped system | Particle sciences | Development |

and certainly many more programs are currently undisclosed within development. One also notes that these programs span a range of applications which includes the use of melt extrusion to replace conventional technologies to advanced drug delivery systems. Such programs illustrate the versatility of hot-melt extrusion, although many areas such as continuous wet granulation, devolatilization, and reactive manufacture remain underutilized. As new chemical entities and drug therapies continue to require advanced technologies, melt extrusion will continue to prove to be a useful technology for enabling drug products. Regulatory initiatives and cost constraints will also utilize the continuous nature of the process to help shape drug delivery in the twenty-first century.

Method Capsule 1

Characterizing Drug Solubility Using Quantitative Preformulation Techniques

Based on the method reported by Suwardie et al. (2011)

Objective

- To determine the melt solubility of acetaminophen in polyethylene oxide using rheological properties of the materials

Equipment and Reagents

- Acetaminophen
- Polyethylene oxide (MW ~ 100,000)
- Oscillatory rheometer (Rheometric Mechanical Spectrometer RMS-800)
- Capillary rheometer
- Differential scanning calorimetry (DSC Q-100)

Method

- Measure dynamic viscosity of a series of acetaminophen drug loadings (0, 10, 20, 30, 40, and 50%) at fixed temperatures (80, 100, 120, and 140°C).
- Measure steady viscosity of a series of acetaminophen drug loadings (0, 10, 20, 30, 40, 5, and 0%) at fixed temperatures (80, 100, 120, and 140°C). Drug loadings of 40% and 50% only evaluated at 120 and 140°C.
- Measure thermal behavior of formulations using a heat-cool cycle from 0 to 100°C at 10°C/min.

Results

- Viscosity curves as a function of drug concentration showed a “V”-shaped inflection that indicated the solubility of drug in molten polymer.
- Increasing stress rates showed a reduction in method sensitivity which indicated that testing for melt solubility should be conducted at low shear.

- High shear conditions were more representative of extrusion conditions and should be studied to evaluate formulation performance under extrusion conditions.
- Small-scale viscosity measurements can be an effective method for evaluating drug solubility in the molten polymer to conserve drug substance in early development.

Method Capsule 2

Dissolution Behavior of Solid Dispersions

Based on the method reported by Alonzo et al. (2010).

Objective

- To study the supersaturated dissolution behavior of felodipine and indomethacin solid dispersions prepared by thermal processing

Equipment and Reagents

- Felodipine
- Indomethacin
- Hypromellose
- Hypromellose acetate succinate
- Polyvinylpyrrolidone K29/32
- Polarized light microscopy
- Raman spectroscopy
- UV spectroscopy

Method

- Solid dispersions were prepared by melt mixing at temperatures 10°C above the drug-substance melting temperature and quench cooling. Material was then cryogenically milled to less than 300 µm.
- Raman spectroscopy was utilized to assess crystalline conversion of solid dispersions in the aqueous environment.
- Nonsink dissolution was performed pION m-Diss Profiler at pH 2 for indomethacin.
- Polarized light microscopy and powder X-ray diffraction were used to investigate recrystallization behavior of solid dispersions in the aqueous environment.

Results

- Amorphous formulations were prepared by melt mixing and quenching.
- Analysis of aqueous slurries showed rapid crystallization of amorphous drug substance which was inhibited by the presence of polymeric additives to the formulation.

- Nonsink dissolution illustrated the ability to supersaturate the aqueous environment.
- Polarized light microscopy showed how crystal growth occurred in supersaturated solutions and could be inhibited by the presence of polymeric additives.

Method Capsule 3

Production of Controlled Release Matrix Systems Using Hot-Melt Extrusion

Based on the method reported by Almeida et al. (2011).

Objective

- To prepare controlled release tablets containing metoprolol tartrate using ethylene vinyl acetate carrier

Equipment and Reagents

- Meoprolol tartrate
- Ethylene vinyl acetate (EVA 9, 15, 28, 40)
- Haake Minilab II Laboratory Scale Hot Melt Extruder

Method

- Extrude formulations at different screw speeds (40, 60, and 90 rpm) and processing temperatures (60, 80, 90, 100, 110, 120, 130, and 140°C) using a 2.0-mm round die.
- Prepare matrices by manual cutting to 2-mm dosage units.
- Evaluate crystallinity and drug distribution using Raman spectroscopy.
- Perform controlled release dissolution testing using USP Apparatus I in purified water.
- Characterize internal porosity of the device using X-ray tomography.

Results

- Control release EVA matrices containing metoprolol tartrate were successfully prepared using hot-melt extrusion at temperatures greater than 100°C to prevent surface defects.
- Metoprolol tartrate was homogeneously distributed in the carrier matrix as a crystalline solid dispersion, although elevated processing temperatures increased the level of amorphous material in the formulation.
- Drug release was effected by drug loading and EVA grade used, with the release mechanism a combination of drug crystallinity and EVA crystallinity which was related to vinyl acetate content.

- Limited changes of internal porosity were the result of elastic recovery and molecular rearrangement during the dissolution process.
- EVA was shown to be a viable material for the production of controlled release matrix systems using hot-melt extrusion.

Method Capsule 4

Production of High-Dose Tablets Containing Melt-Granulated Material

Based on the method reported by Lakshman et al. (2010).

Objective

- To prepare high-dose combination tablets containing metformin HCl granules prepared by continuous hot-melt granulation and a second developmental drug substance.

Equipment and Reagents

- Metformin HCl
- Hydroxypropyl cellulose
- Developmental drug substance (name not disclosed)
- Magnesium stearate
- Thermo-Prism 16-mm Hot Melt Extruder
- Oscillating bar mill
- V-Blender
- Rotary tablet press

Method

- Extrude material in 40:1 configuration using a temperature range less than 180°C through an open discharge outlet.
- Granules were then milled, blending with additional materials and compressed to tablets using the rotary presses.

Results

- Metformin HCl granules were successfully prepared using continuous melt granulation at a drug loading of up to 91%. Solvent-based techniques were not able to successfully match the performance of melt granulation.
- Combination tablets containing granules prepared by hot-melt granulation exhibit greater hardness and reduced friability when compared to tablets prepared at the same compression force containing granules prepared by solvent-granulation techniques.
- Melt granulation was shown to be a useful technique for preparing granulated powders, which would be particularly useful for materials which exhibit sensitivity to moisture.

Method Capsule 5

Melt-Extruded Solid Dispersions for Improved Oral Bioavailability

Based on the method reported by Miller et al. (2008a).

Objective

- To investigate the use of high-molecular-weight stabilizer to improve oral bioavailability of itraconazole.

Equipment and Reagents

- Itraconazole
- Eudragit® L100-55
- Triethylcitrate
- Carbomer 974P
- Haake Minilab II

Method

- Formulations containing 33% itraconazole, Eudragit® L100-55 plasticized with 20%w/w triethyl citrate and varying levels of Carbomer 974P were prepared by hot-melt extrusion at 130°C.
- Extrudate milled and screened to a particle size of less than 250 µm.
- Nonsink dissolution testing was performed using a two-stage acid–phosphate buffer pH 6.8 using USP apparatus II.
- Bioavailability enhancement of formulations was evaluated using male Sprague-Dawley rats at a dose of 30 mg/kg.

Results

- Melt-extruded material was successfully prepared using the Haake Minilab II, yielding amorphous formulations that exhibited multiple T_g 's associated with the solid dispersion and the Carbomer phase.
- Nonsink dissolution showed that Carbomer reduced the rate of dissolution and also extended the duration of supersaturation, with the most effective level being observed at 20% w/w.
- Oral bioavailability was improved with the 20% Carbomer formulation and also exhibited a significant reduction of variability.

Chapter 10

Spray-Drying Technology

Dave A. Miller and Marco Gil

Abstract This chapter provides an in-depth review of spray-drying technology and its application to the formulation of poorly water-soluble drugs. In the early part of the chapter, the fundamentals of the process are discussed, including process theory, process components, equipment options, equipment by scale, various feeds, and typical solvent systems. In the latter part of the chapter, the application of spray drying to the formulation of poorly water-soluble drugs is discussed. Particular emphasis is given to spray drying for amorphous solid dispersion systems. The path toward developing an amorphous spray-dried dispersion and conversion to a final dosage form is covered in detail. Additionally, several academic and industrial examples are presented, illustrating the benefits of the process as a formulation technology and its commercial viability. Finally, the application of spray drying to inhalation as well as emerging applications, i.e., spray congealing and micro-encapsulation, are reviewed. This chapter provides comprehensive coverage of the spray-drying process and its uses as a formulation technology toward the enhancement of drug delivery with poorly water-soluble compounds.

10.1 Background

At its essence, spray drying is a continuous means of extracting dry solids from a fluid by evaporation of the carrier liquid. By this process, one can start with a solution, suspension, slurry, emulsion, low-viscosity paste, or the like and convert it into a

freely-flowing powder in a single step (Celik and Wendel 2005). One of the earliest descriptions of a spray-drying process was published in 1872 in United States Patent 125,406 entitled “Improvement in Drying and Concentrating Liquid Substances by Atomizing.” This patent describes a process whereby a fluid is converted to a state of “minute division” with simultaneous exposure to “currents of air or other gasses” for the purpose of rapidly drying a solid substance from a liquid carrier (Percy 1872). From this early description, spray drying has since evolved into a diverse technology with a long history of successful commercial applications.

Spray drying has been utilized industrially for well over a century and consequently has fully matured and is well understood. Owing to its simplicity, efficiency, and robustness, the technology has been employed in a variety of industries for the production of a vast array of products. It is commonly used to process milk, eggs, ceramics, fertilizers, detergents, and numerous other chemicals (Broadhead et al. 1992). In the pharmaceutical industry, spray drying has been used for the production of bulk actives, including small molecules, vitamins, peptides, and proteins (Celik and Wendel 2005). It has also been employed as a process technology to impart unique functional attributes onto excipients, such as lactose, mannitol, and micro-crystalline cellulose, to name a few. Additionally, spray drying has been employed for the production of novel drug-delivery systems with primary applications in granulation and particle engineering.

Spray drying has recently been the focus of increased interest as a technology applicable to improving bioavailabilities of poorly water-soluble drugs. In this chapter, the utilization of spray-drying technologies toward the enhancement of formulations containing poorly water-soluble drugs is discussed in detail. Particular emphasis is given to the use of spray drying for the formulation of amorphous solid dispersions as this is perhaps the most common application of the technology to this field. In addition, this chapter aims to provide the reader with a basic understanding of the process fundamentals, the various process components, and the equipment options at different scales. For a more detailed discussion regarding the principles of spray drying, the inquiring reader is referred to the “Spray Drying Handbook” by Masters (1985). Finally, this chapter covers emerging applications of spray-drying technology as they apply to the formulation of poorly water-soluble drugs.

10.2 Process Overview

Spray drying consists of feeding a liquid stream (solution, suspension, or emulsion) that is continuously divided in fine droplets (atomization) into a chamber (drying chamber). In the drying chamber, the droplets come into contact with a hot gas and, by an evaporative cooling process, are converted into solid particles. These particles are then separated from the wet drying gas by a suitable separation system, most commonly a cyclone or filter bag. To summarize, the process is divided into four main steps: (1) spray formation – atomization of the feed solution/suspension/emulsion; (2) droplet–gas contact; (3) droplet drying and particle formation; and (4) separation of solid particles from the wet drying gas (Masters 2002). A schematic diagram of the spray-drying process is provided in Fig. 10.1.

Fig. 10.1 Schematic diagram of the spray-drying process

10.2.1 Atomization

Atomization, the generation of very fine droplets from a liquid feed, is a key aspect of the spray-drying process. It substantially increases the liquid surface area to vastly improve the efficiency of heat and mass transfer. For example, one cubic meter of liquid atomized into droplets of 100 μm in diameter yields a surface area of 60,000 m^2 . By the generation of such high surface area, the drying process proceeds rapidly, completing in seconds or fraction of a second depending on equipment scale. Control of the atomization process enables tuning of the droplet size and consequently product particle size. Particle size of a spray-dried product is especially relevant to downstream processing and final dosage form production.

There are several types of atomizers that can be used to produce the feed spray inside the drying chamber. These nozzles are classified according to the type of energy used and include: rotary nozzles (centrifugal energy), two-fluid or pneumatic nozzles (kinetic energy), pressure nozzles (pressure energy), and ultrasonic nozzles (acoustic energy). There are several configurations available for each type of nozzle which are able to produce sprays with specific features. Also, some nozzles combine the use of more than one type of energy to generate the spray. The feed stream properties (viscosity, surface tension, solids load, etc.) impact the degree of atomization achievable for all types of atomizers, but their sensitivity to each feed stream property with regard to droplet size depends on the type of nozzle. In the pharmaceutical industry, the most common nozzles are pneumatic (two-fluid) and pressure nozzles due to their scalability and reduced tendency to generate wall deposits as compared to rotary nozzles.

10.2.1.1 Rotary Nozzles

For rotary nozzles, atomization is achieved by centrifugal energy transmitted to the liquid stream by a disk or wheel rotating at high speed (from 3,000 to 50,000 rpm). The droplets are generated at the edge of the disk/wheel; therefore, the degree of atomization depends primarily on the peripheral speed which is a function of rotational velocity and diameter. Higher speeds are typically used with lower diameter nozzles that are installed in smaller-scale spray driers (Masters 2002).

Rotary nozzles can be used to atomize slurries, suspensions, or solutions of high viscosity. Besides the feed properties, the operating variables that influence droplet size are feed flow, rotational velocity, wheel diameter, and design. The general correlation that can be used to estimate mean droplet size is the following:

$$D_{50}(\mu\text{m}) = KF^x N^{-y} d^{-z} (nh)^{-w} \times 10^4.$$

In this equation, K is a feed related constant; F is the feed flow (kg/h); N is the wheel speed (rpm); d is the wheel diameter; n is the number of vanes, bushings pins, or holes; and h is the height of a vane or pin, or half of the circumference of circular bushing openings (m). The x , y , z , and w parameters are system dependent and must be determined experimentally.

10.2.1.2 Pneumatic Two-Fluid Nozzles

Pneumatic two-fluid nozzles use a gas stream to atomize the feed which explains their designation. The mixing of the liquid stream and the atomizing gas can be performed in the nozzle's tip as depicted in Fig. 10.2a (external mixing two-fluid nozzle) or in a chamber inside the nozzle as depicted in Fig. 10.2b (internal mixing two-fluid nozzle). Although the external mixing two-fluid nozzles are the most common in small-scale and pilot-scale spray driers, the internal mixing nozzles are more efficient and preferred in larger-scale spray driers, especially when small particle sizes (less than 10 micron) are required. In this type of nozzle, the gas mass flow to liquid mass flow ratio (often called the atomization ratio) is used to characterize the degree of atomization.

Correlations have been developed to estimate droplet size produced with two-fluid nozzles based on liquid sheet formation and destabilization through an accelerative mechanism. In the case of two-fluid nozzles, the Sauter mean diameter can be estimated by the following correlation:

$$\text{SMD} = \frac{2\pi}{5} \sqrt{\frac{\sigma \cdot \lambda_{\text{max}}^{KH}}{10 \cdot \rho_g \cdot \left(U_G \cdot \left(1 + \sqrt{\frac{\rho_g}{\rho_l}} \right) - U_L \right)^2}},$$

Fig. 10.2 Pneumatic two-fluid nozzles: (a) external mixing and (b) internal mixing. Image (b) was reproduced with permission from Delavan Spray Technologies and Goodrich Corporation respectively

where σ is the surface tension, λ_{\max}^{KH} is the maximum Kelvin–Helmholtz wavelength, ρ_g is the atomization gas density, U_g is the atomization gas velocity at nozzle tip, ρ_L is the liquid density and U_L is the liquid velocity.

10.2.1.3 Pressure Nozzles

With pressure nozzles the atomization is achieved by transforming pressure into kinetic energy. In spray drying, pressure nozzles are designed to produce hollow swirling sprays; hence, they are also known as pressure-swirl nozzles. They promote rotation through a swirl chamber, which has tangential slots to impart spin on the liquid before exiting the circular orifice.

These nozzles require the use of high-pressure pumps as pressures of up to 450 bar can be required. They may be applied to all types of feeds, but special attention must be paid when spraying suspensions. The size of the suspended material should be controlled to avoid nozzle clogging, nozzle erosion, and/or pump failure. In larger-scale spray driers, these nozzles are good for production of medium to large particles (30–200 μ). They also produce more uniform powders than pneumatic two-fluid nozzles and, therefore, are preferred for the production of powders for oral dosage forms (Fig. 10.3).

Fig. 10.3 Pressure nozzle. Reproduced with permission from Delavan Spray Technologies and Goodrich Corporation respectively

Fig. 10.4 Droplet size and feed flow variation with atomization pressure

The modeling of droplet size for pressure nozzles is more developed than for two-fluid nozzles. This is attributable to the application of pressure nozzles in combustion engines and the optimization of those engines over the years. There are several semi-empirical correlations that can be easily used to estimate droplet size, such as those proposed by Radcliffe, Jasuja and Lefebvre (Jasuja 1979; Lefebvre 1987; Radcliffe 1960). Droplet size can be tuned by adjusting operating pressure, but feed flow is not independent of the pressure. With increasing atomization pressure, the droplet size decreases and feed flow increases. Therefore, the selection of the nozzle size must take into account not only pressure but also feed flow requirements/drying capacity (Fig. 10.4).

10.2.1.4 Ultrasonic Nozzles

Ultrasonic nozzles use acoustic energy to promote vibration of the nozzle tip where the formation of droplets takes place. The droplet size can be tuned by the ultrasound frequency and the nozzle tip design. Their application is primarily for laboratorial-scale spray driers due to two main factors: (1) low droplet velocity enabling drying of larger droplets than two-fluid nozzles and (2) limited spray throughput. An important limitation of these nozzles is that drying temperatures typically limited to less than 110°C.

10.2.1.5 Three- and Four-Fluid Nozzles

Other nozzles are described in the literature featuring specific designs to accomplish particular tasks. The so-called, three-fluid nozzles are described by Kirkpatrick et al. (1986). This nozzle has two different stages of atomization and claims to enable higher solids load and the capability of handling highly viscous feeds. According to its design, a liquid is pre-mixed with the atomization gas creating a primary spray of coarse droplets, not suitable for spray drying. This primary spray is then deflected radially outward by collision with a deflector plate. A second atomizing gas stream, concentric to the deflector, promotes further breakup of the primary spray, thus creating a fine spray suitable for spray drying.

A four-fluid nozzle has also been described in the literature by Mizoe et al. (2008). This nozzle has two liquid and two gas passages and claims the capability to produce droplets of single micron diameters. However, the most interesting feature of this nozzle is the possibility to feed two liquid streams. This enables the production of solid dispersions by spray drying where the active ingredient and the polymer are not dissolved in the same solvent (Mizoe et al. 2008).

10.2.1.6 Monodisperse Nozzles

All of the nozzles described above produce polydisperse sprays; however, small and uniform particles are required for certain applications, such as high-efficacy drug micro-capsules, colloidal drug delivery, and dry formulation vehicles. For these cases, the application of monodisperse droplet generators (MDGs) further enhances the utility of spray-drying technology (Wu et al. 2007). MDGs were originally developed based on ink-jet printing technology (Le 1998). The technology has since improved and the nozzle has found applications in other areas. Among those are the development of mechano-hydrodynamic droplet generators associated with piezo-electric transducers that enable the production of fine mono-droplets (Wu et al. 2007). Other systems are based on laser-drilled orifices and are used in the production of micro-chips, e.g., Nanomi microsieve™ (spans of less than 1.0 were achieved with PLGA particles). However, these systems are still restricted to laboratorial

Table 10.1 Comparison between types of atomizers

| Nozzle type | Rotary | Two-fluid | Pressure | Ultrasonic |
|---|----------------------|---------------------------------------|--|---------------|
| Scale | Pilot/ Industrial | Laboratorial/ Pilot/ Industrial | Pilot/Industrial | Laboratorial |
| Mean droplet size range (μm) | 10–500 | 1–100 | 10–400 | 5–1,000 |
| Viscosity | High | High | Medium (<750 cP) | Low (<~50 cP) |
| Ability to handle suspensions | Yes | Yes | Depends on suspended particles size. A filtration step may be required to prevent clogging. Erosion must also be considered. | Yes |

applications mainly due to cost and low throughput. Throughput is limited with these systems because the Ohnesorge and Reynolds numbers must be within certain ranges to achieve the mono-disperse droplet regimen.

10.2.1.7 Atomizer Selection

Selection of the appropriate atomizer depends on the following:

- Feed properties (suspended particles, viscosity, rheologic behavior, etc.)
- Feed flow capacity requirements
- Particle-size distribution requirements
- Air disperser design of the spray-drying unit (see section Air dispersers)

A comparison between the different atomizers is provided in Table 10.1. The most common atomizers used in lab scale are the pneumatic two-fluid nozzles due to their simplicity and flexibility. At industrial scales in the pharmaceutical industry, pressure nozzles are more frequently used due to their narrower particle-size distributions.

10.2.2 Gas-Droplet Contact

There are two configurations for spray drying, depending on the direction of the drying gas flow and the feed being atomized: (1) co-current and (2) counter-current, as depicted in Fig. 10.5. In co-current configuration, the inlet drying gas and atomized feed stream both originate from the top of the drying chamber. The droplets descend with the drying gas and exit through the bottom of the drying chamber.

Fig. 10.5 Spray-drying configurations: (a) co-current and (b) counter-current

In counter-current mode, the atomized feed and the drying gas originate from opposite ends of the drying chamber. By this configuration, residence time in the drying chamber is increased. Of the two configurations, co-current is the most commonly used in the pharmaceutical industry because residence time is shorter and, therefore, particles are subjected to less thermal stress.

10.2.2.1 Gas Dispersers

Gas dispersers are very important in the spray-drying unit because they define the air flow pattern inside the drying chamber, especially near the nozzle (in the co-current flow spray driers). They are located just before the entrance of the drying gas into the chamber and impact the drying efficiency, particle residence time, and droplet/particle collisions. It is crucial to have a uniform distribution of the drying gas flow inside the chamber to achieve homogeneous drying of the droplets. Otherwise, wall deposits can occur leading to lower yields.

Gas disperser design has been evolving over the years, with recent advances realized by the application of computational fluid dynamics. The most optimum design depends on the configuration of the spray drier (co-current or counter-current) and the atomization nozzle to be installed. Since co-current spray driers equipped with pneumatic or pressure nozzles are the most commonly used in the pharmaceutical industry, only this case will be discussed.

The dispersers in these cases can be divided into two groups depending on the flow pattern. One design creates a rotation pattern around the atomization nozzle

(suitable for rotary, pneumatic, and pressure nozzles). This rotation improves the solvent evaporation capacity but promotes recirculation of powder at the top of the chamber potentially leading to product deposits on the ceiling. Also, in the case of low-density particles, the swirling air pattern significantly increases the residence time of powder inside the chamber. This swirling pattern can also lead to product adhesion and buildup at the nozzle tip that, in severe cases, can obstruct the atomization nozzle.

The other type of disperser aims to provide streamlined flow parallel to the chamber's vertical axis. The chambers associated with this disperser type are usually taller than those coupled to rotational dispersers due to the flow pattern. The main advantage of this disperser type is reduced wall deposit formation. In terms of design, the most common streamlined air dispersers are based on perforated plates or guide vanes. The former can be very efficient in providing laminar vertical flow of the drying gas, but application in the food and pharmaceutical industry is limited by cleaning challenges. The latter is preferred for the pharmaceutical industry due to its sanitary design and lower-pressure drop over the disperser (Hansen 2009).

The chamber dimensions depend on the atomizer and air disperser design as described previously. However, another important feature is the safety data of the product to be handled, e.g., explosivity and auto-ignition. In some extreme cases, the chamber has to be equipped with suppressant and/or pressure-relief systems. These systems are typically preferred, because the construction of chambers with high-pressure shock ratings is very expensive.

10.2.3 Collection Systems

After exiting the drying chamber, the powder must be collected by appropriate systems. The most appropriate collection system depends on handling requirements and product characteristics, e.g., particle size and density. There are three main types of collectors based on different separation techniques: centrifugal force (cyclones), filtration (filter bags), and electrostatic precipitators.

10.2.3.1 Cyclones

The most common collection systems used in pharmaceutical spray drying are cyclones. In this system, the gas coming from the drying chamber enters tangentially creating a downward vortex that, through centrifugal forces, sweeps the material against the walls. In this way, the dried particles are collected in the bottom of the cyclone. At the same time, the gas reverses direction and travels upward to the top of the cyclone forming an inner vortex (lower pressure region). This upward current leaves the system as exhaust gas carrying with it entrained particles and solvent vapors. Both capital investment and operating costs are low for cyclones as compared to other collection systems. Moreover, recent developments in design have further increased their efficiency (Salcedo and Pinho 2002).

Cyclone efficiency curves constructed with data from specific products are generally available as a function of particle size (Masters 2002). These curves are plots of collection percentage versus particle diameter enabling the relative comparison between cyclones. These efficiencies cannot be directly correlated with spray-dried products due to differences in true density and omission of agglomeration effects often encountered with pharmaceutical spray-dried products. However, there are correlations that enable the correction of these plots that achieve very precise estimations of efficiency. Particle agglomeration effects are one of the reasons that cyclone efficiencies are often higher than would be expected from manufacturers' efficiency curves. A typical spray-drying system in the pharmaceutical industry is equipped with a single cyclone. However, several cyclones can be utilized in parallel or in series to increase collection efficiency. Very high performance cyclones exist for particle sizes of about 5 microns that can yield collection efficiencies greater than 95%. These cyclones are particularly well suited for inhalable products.

Cyclone efficiency also depends on gas velocity as this influences the pressure drop, which is typically between 70 and 250 mm H₂O. Therefore, for a given system, cyclone efficiency may be improved by increasing drying gas flow rate or by adding an extra gas stream before the cyclone. However, this is limited by the capacity of the ventilators to handle such increases in gas flow.

The "cutoff" point of a cyclone is the particle size at which it can only capture 50% of the product particles. This metric is also a straightforward means of comparing performance. Major product losses may occur if there are leaks in the bottom of the cyclone or if the base of the cyclone becomes obstructed by product. For the later, the inner vortex carries the product to the exhaust leading to potential for significant losses. Systems may be implemented to avoid obstruction of the exit orifice such as hammering devices at the discharge.

As in the drying chamber, some products tend to stick to the walls of the cyclone. This aspect can be especially critical with thermoplastic products, and particularly in the case of solid dispersions when the drying temperature is relatively close to the glass transition temperature. It can also be an issue when relative solvent saturation levels in the drying gas are high.

10.2.3.2 Filter Bags

Filter bags are typically incorporated into spray-drying systems downstream of the cyclone to filter out entrained particles in the exhaust gas. This prevents powder from exiting into the environment or contaminating auxiliary equipment (ventilators, condensers, heaters, etc.). Filter bags consist of a number of bags (depending on the drying gas flow and bag permeability) installed inside a rigid container. To facilitate continuous operation, a dry clean-in-place system is usually installed. This consists of a pulsed flow of a pressurized gas (same type and grade as drying gas) that dislodges the powder entrained in the bags. Depending on the product being spray dried and the material of construction of the bags, the efficiencies of these cleaning systems vary.

Table 10.2 Collection efficiencies for different collection systems

| Particle size | 10 μ | 5 μ | 1 μ |
|-----------------------------|----------|---------|---------|
| High-efficiency cyclones | 95–100% | 90–95% | 10% |
| Filter bags | 100% | 100% | 99 |
| Electrostatic precipitators | 100 | 99 | 86 |

In terms of powder collection efficiency, filter bags can collect finer particles than cyclones irrespective of particle density. However, for some products, namely those intended for inhalation or parenteral administration, its use as a primary collection system may not be adequate. In these cases, special types of bag materials have to be tested and assessed for the release of fine particles.

The selection of construction materials for the filters depends on the chemical properties of the product being collected and the outlet drying temperature. Typically, filter bags are constructed of polyester fibers which have a maximum operating temperature of approximately 130°C and are highly resistant to acids, bases, and microbial growth. When higher operating temperatures are required, Teflon filters are preferred; however, they are also more expensive.

Filter bags require greater capital investment and maintenance costs than cyclones (some systems include 24 filters per bag house), but the balance is favorable for high-cost products if they provide a significantly better product yield. Even if not the primary collection system, filter bags are widely used downstream of cyclones to remove airborne particles from the exhaust of laboratorial, pilot, and industrial scale units.

10.2.3.3 Electrostatic Precipitators

Electrostatic precipitators create an electrical field through which the spray-dried powder passes, thereby charging the particles which subsequently adhere to oppositely charged plates. These systems are found in some laboratorial units to collect very small particles (nanoparticles). Despite their high recovery efficiencies, even for very small particles (particles in the nanometer size range included), electrostatic precipitators are rarely used in industrial-scale pharmaceutical spray drying. This might be explained by the high capital and operating costs and by the fact that the previously described systems provide high collection efficiencies in a great majority of cases (Table 10.2).

10.2.4 Closed-Loop Versus Open-Loop Systems

The most common spray-drying configuration found in industry is the open-loop system. In this system, the drying gas is used only once and is then exhausted to the atmosphere after appropriate post-treatment. However, in the pharmaceutical industry and especially with the production of solid dispersions, the closed-loop configuration

Fig. 10.6 Product residual solvent as a function of drying gas relative saturation

(drying gas is re-heated after solvent removal and re-introduced in the drying chamber) is most typical. In these systems, flammable organic solvents are often used; therefore, an inert gas (nitrogen) must be used as the drying medium. In the closed-loop layout, gas consumption is minimal as compared to the open-loop configuration and is, therefore, more cost effective in regular operation despite greater initial investments.

The closed-loop configuration requires removal of solvent vapors from the drying gas before it can be reintroduced into the drying process. Several systems can be used for this operation, with the most common being condensers with adjustable temperatures. In the condenser, the drying gas is cooled to a target temperature at which point the gas becomes saturated with the solvent. The condensed solvent is then removed and the drying gas is reheated and reintroduced in the drying chamber. In closed-loop systems, the amount of solvent being re-circulated is not negligible, especially in the case of organics. This must be considered when generating the heat and mass balances.

The saturation level of drying gas for a given feed flow and drying temperature is always higher in a closed-loop configuration (can be as high as 50% relative saturation at the outlet of the drying chamber). Thus, the residual solvent level in the spray-dried solids is also higher in these units. A plot illustrating the influence of solvent content in the drying gas on residual solvent in the product is provided in Fig. 10.6.

10.3 Equipment by Scale

10.3.1 Laboratory-Scale Equipment

Laboratorial-scale spray driers are useful for producing small quantities of prototype formulations in early-stage development. They can process very small quantities of solution (as low as 0.25 ml) with relatively high yield. Since spray drying is

a continuous process, all units provide flexibility with respect to batch size. Therefore, these small units are also capable of spray drying much greater quantities of feed by running continuously for extended durations. Another unique feature of these systems is that, the drying chamber and cyclones are typically constructed of glass, thus enabling visualization of the drying process.

In Table 10.3, a list of the most common laboratorial-scale equipment found in the market is presented. The maximum drying gas flow rate is approximately 30 m³/h which enables the drying of about 1 L/h of water (higher for organic solvents).

The standard atomization system for these units is the two-fluid nozzle, but in some models, ultrasonic (Mini Spray drier B-290, 4 M8-TriX), piezoelectric (Nano Spray Dryer B-90), or mono-disperse nozzles (4 M8-TriX) can also be found.

Another important feature of these units is the collection system. Cyclones are the most common collection systems used. Some manufacturers offer the choice of different cyclones providing a range of collection efficiencies. The Nano Spray Dryer B-90 is the only unit capable of producing particles in the nanometer range. In order to provide acceptable product yields for these fine particles, the system is equipped with an electrostatic particle collector, enabling recovery yields of up to 90%.

Process scale-up from laboratorial-scale to pilot- and large-scale spray driers has been studied by several authors. The main challenge in scale-up is related to particle size. The small dimensions of the drying chambers limit the residence time distribution. Therefore, the atomized droplets must be small in order to complete the drying process prior to exiting the chamber or impacting the chamber walls. Typically, the drying gas flow pattern in the smaller units is not laminar which causes the droplets/particles to collide with the chamber walls. This further reduces the duration for drying of the atomized feed. The Nano Spray Dryer B-90 and 4 M8-TriX units claim to provide laminar flow patterns which is a great advantage not only in terms of yield but also with regarding to utilizing the full chamber length to enable production of larger product particles. However, only the 4 M8-TriX spray drier, when coupled with an ultrasonic nozzle, claims to be capable of producing particles in the same size range as large-scale units (up to 100 μm).

10.3.2 Pilot-Scale Equipment

Pilot-scale spray driers are suitable for batch sizes from hundreds of grams up to about 20 kg. These units are very similar to production-scale equipment with regard to configuration and material of construction, i.e., they are composed of stainless steel as opposed to lab-scale, glass units. These units consume significant drying gas and therefore should be operated in the closed-loop configuration when using nitrogen (required for drying organic solvents).

Examples of pilot-scale spray driers available in the market are shown in Table 10.4. The suppliers offer many possible system configurations (closed loop, open loop, mirror polishing, aseptic versions, clean in place, etc.) as well as different atomization systems. Pressure nozzles, as mentioned previously, produce a more

Table 10.3 Laboratory-scale spray dryers

| Designation | Manufacturer | Drying gas flow (kg/h) | Evaporation capacity (Liter H ₂ O/h) | Possible particle-size diameter | Smallest sample | Closed loop | Collection system |
|------------------------|--------------|------------------------|---|---------------------------------|-----------------|-------------|-------------------|
| Mini Spray Dryer B-290 | Büchi | 40 | 1.0 | 1–25 µm | 30 ml | Yes | Cyclone |
| Nano Spray Dryer B-90 | Büchi | 12 | 0.2 | 0.3–5 µm | 1 ml | Yes | Electrostatic |
| SD Micro™ | Niro | 30 | 1.0 | – | 100 ml | No | Cyclone |
| MicraSpray | Anhydro | 30 | 1.0 | – | 100 ml | No | Cyclone |
| Spray dryer 4 M8-TriX | Procept | 36 | 1.0 | 1–100 µm | 0.25 ml | No | Cyclone |
| GS-310 | Yamato | 40 | 1.3 | – | – | Yes | Cyclone |

Table 10.4 Pilot-scale spray dryers

| Designation | Manufacturer | Drying gas flow (kg/h) | Evaporation capacity (Liter H ₂ O/h) | Maximum inlet temperature (°C) | Atomization systems | Closed loop |
|----------------|--------------|------------------------|---|--------------------------------|--|-------------|
| Mobile Minor | Niro | 80 | 7 | 350 | Rotary Two-fluid Pressure ^a | Yes |
| MicraSpray 75 | Anhydro | 75 | 2 | 200 | Two-fluid | Yes |
| MicraSpray 150 | Anhydro | 150 | 14 | 350 | Rotary Two-fluid | Yes |

^aRequires a chamber extension to use pressure nozzle atomization

Table 10.5 Spray-drying evaporation capacity for the most common solvents

| Drying gas flow (kg/h) | Water (kg/h) | Ethanol (kg/h) | Acetone (kg/h) | Dichloromethane (kg/h) |
|------------------------|--------------|----------------|----------------|------------------------|
| 360 | 18 | 45 | 75 | 118 |
| 630 | 35 | 75 | 130 | 200 |
| 1,250 | 70 | 160 | 275 | 400 |
| 4,000 | 220 | 575 | 900 | 1,300 |

homogenous particle-size distribution and higher-density powders. Therefore, those units that enable the use of this atomization system are preferred for spray-dried products used in oral dosage forms.

Evaporation capacity of these units depends on the drying gas flow and maximum inlet temperature. The Niro Mobile Minor has a higher evaporation capacity due to the maximum inlet temperature (350°C) when compared to the MicraSpray 75 (maximum temperature (200°C). However, in the pharmaceutical industry, the use of such high temperature is not recommended in most cases. For a given temperature, the evaporation capacity depends on the drying gas flow, which is very similar for these two units.

10.3.3 Production-Scale Equipment

Production-scale equipment have all the features as the pilot-scale units; however, given their larger size they are more flexible in terms of manipulation of product properties, e.g., particle size and density. Taking advantage of the larger dimensions of the drying chamber, the use of pressure nozzles, instead of two-fluid or rotary nozzles, is a standard at this scale.

Spray-drier manufacturers have specialized their equipment to the pharmaceutical industry creating, in some cases, specific pharma lines of equipment. Such equipment is available in a wide range of production scales from 360 to 4,000 kg/h of nominal drying gas capacity, enabling the evaporation of more than 200 kg/h of water. In Table 10.5, the evaporation capacity for various solvents at varying production-scale drying gas flow rates is presented.

10.4 Feeds

A wide range of feed types can be spray dried. They can be solutions, suspensions, emulsions, or mixtures thereof. In the case of solid dispersions, a solution of active ingredient and excipient(s) dissolved in a common solvent system is the most typical feed. Some important parameters to take into account for feed systems are:

- Solids load – This is primarily governed by the solubility of the constituents in the solvent system as well as the viscosity of the resulting solution.
- Viscosity – Very high viscosity solutions can be spray dried, but the atomization system must be properly selected (see Atomization).
- Solvent system – All volatile solvents are suitable for spray drying. The use of inert drying gas and intrinsically safe equipment enables safe drying of organic solvents.

The typical solids load in a spray-drying process is between 5 and 50% (w/w). The higher the solids load, the more cost-effective will be the process because spray-drying capacity is mainly limited by solvent evaporation capacity. The other potential benefit of using higher concentrations in the feed is the possibility to produce larger particles that have better flow properties.

Regarding viscosity, it is chiefly determined by the excipients (polymers, cyclodextrins, etc.) used in solid dispersions. Many of them exhibit non-Newtonian behavior, namely shear thinning and/or extensional thickening properties. This impacts the atomization process and may introduce some challenges in this regard.

The most common solvents used are low-boiling-point solvents such as water, ethanol, methanol, and acetone. Other solvents, such as tetrahydrofuran and dichloromethane, may also be used, but special handling or waste-treatment requisites must be taken into consideration. In the next section, common solvents utilized in spray drying are discussed in detail.

10.5 Solvents

A frequent challenge in developing amorphous solid dispersions by spray drying is to find a suitable solvent system that dissolves, in an appreciable amount, both drug and polymer. In fact, many poorly water-soluble drugs also have very limited solubility in organic solvents. Therefore, binary and ternary solvent mixtures are often required to achieve solution concentrations compatible with an industrial spray-drying process. It is important to emphasize that spray-drying capacity is measured in terms of solvent evaporation and independent of solids throughput. Thus, the higher the solids concentration, the more economical will be the process since higher feed flows can be used resulting in greater solids dried per unit time.

In the case of solid dispersions, the solution concentrations range from 5 and 50% (w/w), with a substantial majority of processes being effectively run between 10 and 20% (w/w). The upper limit of concentration is dictated not only by the

Table 10.6 Vaporization enthalpies and boiling points for most common solvents

| Solvent | ΔH_{vap} (kJ/mol) | Boiling point ($^{\circ}\text{C}$) |
|--------------------|----------------------------------|--------------------------------------|
| Water | 40.7 | 100.0 |
| Dichloromethane | 28.0 | 39.8 |
| Acetone | 29.1 | 56.2 |
| Methylethyl ketone | 31.2 | 79.64 |
| Methanol | 35.3 | 65.0 |
| Ethanol | 38.7 | 78.5 |
| Tetrahydrofuran | 29.6 | 67.0 |
| Ethyl acetate | 31.9 | 77.1 |

components' solubilities, but also, in some cases, by the viscosity of the solution which can adversely effect the atomization process.

Water is the solvent of choice whenever possible for a spray-drying processes because it is an environmentally friendly solvent, does not require the use of inertized systems, and upon evaporation requires only a filtration step before being exhausted to the atmosphere. Also, open-loop systems are suitable for drying of water-based feeds even for large-scale production, e.g., milk powder. However, for obvious reasons it is of very limited use for the production of solid dispersions by spray drying being only seldom employed as a co-solvent in binary or ternary solvent systems.

All International Conference on Harmonization (ICH) class II and III solvents (see Sect. 10.5.7) are suitable for use in the spray-drying process. The most volatile are preferred due to the higher throughputs that can be achieved, and because they enable the use of lower drying temperatures. The latter aspect is important when processing low glass transition products as it results in higher process yields, less potential for product sticking to equipment walls, and less potential for partial drug crystallization.

The most common solvents used in the spray drying of solid dispersions include: alcohols (e.g., methanol, ethanol, and isopropanol), ketones (e.g., acetone and methyl ethyl ketone), dichloromethane, tetrahydrofuran, and ethyl acetate. At the end of the spray-drying process, the residual solvent content of the powder is almost always above the admissible limits set by the ICH. Therefore, a secondary drying step is often required to decrease the solvent content. However, this must be assessed in an early stage of development, because residual solvent removal can be very difficult to achieve and, in some cases, is impossible to remove to the required safety limits. In these instances, a change of solvent would be needed. The various solvents and their respective enthalpies of vaporization and boiling points are tabulated in Table 10.6.

10.5.1 Alcohols

Alcohols are polar protic solvents widely used in spray drying. Methanol and ethanol are the most used alcohols for this purpose due to their low boiling points and good

solubilization properties. Relatively low drying temperatures (outlet temperatures of 30–40°C) can be used to evaporate these solvents in the spray-drying process. Also, given that their freezing point is very low (<−98°C), the condenser temperature in the closed cycle spray-drying units can be very low (<0°C) and limited only by the capabilities of the cooling system.

10.5.2 Ketones

Ketones are polar aprotic solvents that are also widely used for spray drying, namely acetone and methylethyl ketone. Given the good solubility of HPMCAS in acetone this solvent is widely used for the production of solid dispersions by spray drying. For instance, torcetrapib referred to in Sect. 10.8.11.4, was spray dried from a solution of HPMCAS in acetone. Relatively low drying temperatures may be used (outlet temperatures of 30°C are common for this solvent) which enables the production of relatively dense powders. In terms of spray drying, methyl ethyl ketone has similar properties to acetone but has a higher boiling point and can provide higher solubilities with some drugs. Similarly to alcohols, very low temperatures in the drying condenser are acceptable with ketones.

10.5.3 Dichloromethane

Dichloromethane (DCM) is a very complementary solvent to alcohols and ketones due to its lack of oxygen atoms. It provides good solubilization properties for certain drugs and polymers, and it enables the use of very low drying temperatures (outlet temperatures around 20°C may be used) due to its low boiling point (39.8°C). Also, according to its low boiling point and evaporation enthalpy, spray drying of DCM is highly efficient, thus making it a favorable solvent for processing large quantities. Its evaporation capacity is seven times greater than that of water for a given spray-drying unit, i.e., a unit that can dry 70 kg/h of water is able to dry approximately 400 kg/h of DCM. However, the requirement for very low residual levels in pharmaceutical products (see Table 10.8) and associated environmental hazards may limit its use.

10.5.4 Tetrahydrofuran

As insolubility becomes a greater issue in drug development, tetrahydrofuran (THF) is becoming a solvent of choice for spray drying. In terms of volatility, it is very similar to acetone (vaporization enthalpy of 29.6 kJ/mol and 19.1 kJ/mol, respectively), although it has a higher boiling point (67.0°C vs. 56.2°C). Nevertheless, it

readily forms explosive peroxides; thus, appropriate safety measures must be in place to process this solvent at an industrial scale. Anti-oxidants (stabilizers) are often added to THF to prevent peroxides formation in order to further reduce the explosion hazard. These anti-oxidant stabilizers, e.g., BHT, have high boiling points and thus become concentrated in the final spray-dried product. Removal is sometimes impossible; hence, their toxicity must be balanced with the product daily dose.

Due to its miscibility with water, tetrahydrofuran is often used in binary THF:water solvent systems. This system is easily spray dried, but care should be taken in optimizing drying temperatures as many times it produces low-density, broken particles. In some cases, THF can be difficult to remove from the product to levels permissible by ICH guidelines. Therefore, it is recommended to evaluate a secondary drying step at an early stage of development.

10.5.5 Mixed Organic Solvent Systems

It is not uncommon to find that a mixture of organic solvents must be used to achieve solubility of the drug and polymer at the desired solids concentration. In principle, all combinations are suitable for spray drying as long as the solvents are miscible (specifically required for amorphous solid dispersions). Binary and ternary diagrams can be generated with common process software to predict miscibility of complex systems. However, for the sake of process robustness, processing close to those limits should be avoided and variations in temperature should be accounted for in the design of the system. Binary solvent systems, such as acetone:DCM, ethanol:water, THF:water, and methanol:acetone, have been widely reported, to mention a few. Usually, these systems are more complex to optimize, but they usually compensate in process robustness and throughput.

10.5.6 Aqueous Systems

In cases where poorly soluble drugs are weak acids or bases, aqueous solvents can occasionally be used for spray drying. Good candidates for this type of aqueous drying are drugs having reasonable solubility in acidic media (weak bases) or alkaline buffer systems (weak acids). In these cases, the drug and excipients are co-dissolved in the acidic or buffered system and spray dried from solution per normal operation. Common aqueous solvents for this application are dilute hydrochloric acid and mildly alkaline buffer systems.

The key benefit to using aqueous solvent systems; aside from the obvious toxicity, environmental, and cost benefits associated with avoiding organic solvents, is that air can be used as the drying gas. This aspect further improves the cost efficiency of the spray-drying operation, as mentioned previously. The potential disadvantages of using acid or alkaline buffer for spray drying are instability of the drug and/or excipients in acidic or basic solutions, and detrimental effects on the formulation

Table 10.7 Allowable limits of class 1 solvents in pharmaceutical products. Adapted from ICH (2011)

| Solvent | Allowable Concentration (ppm) | Issue |
|-----------------------|-------------------------------|---------------------|
| Benzene | 2 | Carcinogen |
| Carbon tetrachloride | 4 | Toxic/environmental |
| 1,2-Dichloroethane | 5 | Toxic |
| 1,1-Dichloroethane | 8 | Toxic |
| 1,1,1-Trichloroethane | 1500 | Environmental |

(chemical stability or release profile) resulting from acid or buffer salt content in the formulation after drying. Despite these disadvantages, aqueous-based solvent systems can be used for spray drying of poorly water-soluble drugs. Being that these types of weakly basic or acidic drugs have solubility within the physiological pH range, the primary benefit of spray-dried dispersions of these molecules is more related to reducing pharmacokinetic variability rather than improving exposure.

10.5.7 ICH Guidelines on Residual Organic Solvents

In *Impurities: Guidelines for Residual Solvents, Q3C(R5)*, the ICH provides recommendations for acceptable amounts of residual solvents in pharmaceuticals for patient safety (ICH 2011). The guideline recommends the use of less toxic solvents and sets the standards for levels of residual solvents that are considered toxicologically acceptable. The guideline defines residual solvents in pharmaceutical products as: “organic volatile chemicals that are used or produced in the manufacture of drug substances or excipients, or in the preparation of drug products...that are not completely removed by practical manufacturing techniques” (ICH 2011). The guidance states that because residual solvents provide no therapeutic effect, they should be removed from the product to meet the requirements of all quality-based specifications or practices. Further, drug products should contain no more residual solvent than can be supported by safety data. This guideline classifies organic solvents into three classes which will be discussed below. The reader should consider that the following sections are merely brief summaries of aspects of the ICH guideline. The actual guideline should be consulted when evaluating a drug product intended for consumption.

10.5.7.1 Class 1 Solvents

Class 1 solvents are “known human carcinogens, strongly suspected human carcinogens, and environmental hazards.” (ICH 2011). They should be avoided in the production of drug products unless there is strong justification based on a risk to benefit assessment. The concentrations of class 1 solvents in drug products should be limited according to Table 10.7.

Table 10.8 Allowable limits of class 2 solvents in pharmaceutical products. Adapted from ICH (2011)

| Solvent | Permitted daily exposure (mg/day) | Concentration limit (PPM) |
|-----------------------|-----------------------------------|---------------------------|
| Acetonitrile | 4.1 | 410 |
| Chlorobenzene | 3.6 | 360 |
| Chloroform | 0.6 | 60 |
| Cumene | 0.7 | 70 |
| Cyclohexane | 38.8 | 3880 |
| 1,2-Dichloroethane | 18.7 | 1870 |
| Dichloromethane | 6.0 | 600 |
| 1,2-Dimethoxyethane | 1.0 | 100 |
| N,N-Dimethylacetamide | 10.9 | 1090 |
| N,N-Dimethylformamide | 8.8 | 880 |
| 1,4-Dioxane | 3.8 | 380 |
| 2-Ethoxyethanol | 1.6 | 160 |
| Ethyleneglycol | 6.2 | 620 |
| Formamide | 2.2 | 220 |
| Hexane | 2.9 | 290 |
| Methanol | 30.0 | 3000 |
| 2-Methoxyethanol | 0.5 | 50 |
| Methylbutyl ketone | 0.5 | 50 |
| Methylcyclohexane | 11.8 | 1180 |
| N-Methylpyrrolidone | 5.3 | 530 |
| Nitromethane | 0.5 | 50 |
| Pyridine | 2.0 | 200 |
| Sulfolane | 1.6 | 160 |
| Tetrahydrofuran | 7.2 | 720 |
| Tetralin | 1.0 | 100 |
| Toluene | 8.9 | 890 |
| 1,1,2-Trichloroethene | 0.8 | 80 |
| Xylene | 21.7 | 2170 |

10.5.7.2 Class 2 Solvents

Class 2 solvents are described as: “non-genotoxic animal carcinogens or possible causative agents of other irreversible toxicity such as neurotoxicity or teratogenicity... Solvents suspected of other significant but reversible toxicities.” (ICH 2011). Although these solvents are considered less harmful than class 1 solvents, exposures should be limited to avoid toxic effects. Consequently, class 2 solvents are limited in concentration in pharmaceutical products. The allowable limits of various Class 2 solvents in pharmaceutical products are listed in Table 10.8.

10.5.7.3 Class 3 Solvents

Class 3 solvents are described by the ICH guidance as: “Solvents with low toxic potential to man; no health-based exposure limit is needed.” (ICH 2011). This class

Table 10.9 Class 3 solvents; daily permitted exposure > 50 mg

| Acetic acid | Heptane |
|------------------------|-----------------------|
| Acetone | Isobutyl acetate |
| Anisole | Isopropyl acetate |
| 1-Butanol | Methyl acetate |
| 2-Butanol | 3-Methyl-1-butanol |
| Butyl acetate | Methylethyl ketone |
| tert-Butylmethyl ether | Methylisobutyl ketone |
| Dimethyl sulfoxide | 2-Methyl-1-propanol |
| Ethanol | Pentane |
| Ethyl acetate | 1-Pentanol |
| Ethyl ether | 1-Propanol |
| Ethyl formate | 2-Propanol |
| Formic acid | Propyl acetate |

Adapted from ICH (2011)

contains no solvents that are known health hazards to humans at typical levels in pharmaceutical products. However, data concerning toxicity from long-term exposure are lacking for many of these solvents. The permitted daily exposure of class 3 solvents is 50 mg or more. These solvents should be used preferentially over class 1 and 2 solvents whenever possible. The acceptable concentration of a class 3 solvent in a drug product should be dictated by GMP and/or product quality standards (Table 10.9).

10.6 Residual Solvent Content and Secondary Drying

Although spray drying is a highly efficient process for separating solids from a solvent system, it is typical for some amount of residual solvent to remain in the dried product. The residual solvent amount can vary in the range of a few parts per billion up to several percent of the dry powder weight depending on the solvent(s), solid(s), and processing conditions. In addition to the potential toxicity issues discussed previously, residual solvents can also adversely impact product quality. In this section, quality concerns posed by excessive residual solvent are discussed along with methods for secondary drying of spray-dried materials to reduce or eliminate residual solvent.

10.6.1 Influence of Residual Solvents on Product Quality

The allowable product concentration limits for class 1 and 2 solvents are determined according to safety and are sufficiently low not to pose any product quality issues. For Class 3 solvents, the allowable product concentrations are not trivial and can have a significant influence on product quality. Residual solvents can present product quality issues such as color changes, odors, chemical instability, and physical instability (Witschi and Doelker 1997). The issue of physical instability is particularly

critical for amorphous spray-dried systems, i.e., amorphous spray-dried dispersion (ASDD) of a drug in an excipient (usually a polymer) carrier.

It has been demonstrated in the scientific literature that organic solvents tend to be efficient polymer plasticizers (Wicks 1986). As such, they can significantly reduce the T_g of an amorphous drug–polymer composite at low concentrations. The correlation between composite T_g and the physical stability of drugs in an amorphous solid dispersion has been well established in the pharmaceutical literature (Matsumoto and Zografi 1999; Yoshioka et al. 1994). An ASDD-based product containing excessive residual solvent may therefore be at greater risk for recrystallization of the drug on storage. Hence, it is understood that reducing residual solvent content in ASDDs is critical not only for safety reasons but for product quality as well.

In order to understand the influence of residual solvent on product stability, an experimental design should be executed to evaluate the physical stability of the ASDD with varying residual solvent content. The ASDD product should be produced at conditions to generate variations in residual solvent content. Powders with a range of solvent content below the limits set according to toxicity should be stored at accelerated conditions and monitored periodically for the appearance of drug precipitation/crystallization. This study will allow for the establishment of product quality specifications for maximum residual solvent content.

There are several different methods for measuring residual solvent content in pharmaceutical products. A detailed discussion of these methods is beyond the scope of this chapter. For a comprehensive review of these methods, the reader is referred to the review article by Witschi and Doelker (1997).

10.6.2 Secondary Drying

Residual solvent levels must be controlled to ensure safety and product quality. Secondary drying of spray-dried product is often required to reduce residual solvent levels to meet product safety and quality specifications. The various equipment choices for secondary drying and their applicability at different scales will be discussed in the following section.

10.6.2.1 Tray Drying

Perhaps the simplest method for removing residual solvent from spray-dried powder is tray drying. In practice, tray drying is accomplished by spreading the bulk powder on trays and drying in an oven at elevated temperatures for a time interval sufficient to reduce the residual solvent to the specified concentration. During the process, loss on drying measurements are performed intermittently to estimate the drying endpoint, and the final residual solvent determination is performed by a suitable method, such as gas chromatography (GC).

Tray drying in a typical convection oven employs both convection and conduction methods to dry the powder mass. In a typical convection oven, forced hot air is used to transfer heat to the drying trays, and also directly to the powder bed. Heat is then exchanged by conduction from the heated surfaces of the drying trays to the powder mass. By these heat exchange processes, residual solvent contained in the spray-dried powder is vaporized and then transported from the oven to the exhaust. For this type of system, both solid bottom and perforated trays can be used. Paper or a suitable screen is often placed over the bottom of a perforated tray to support the powder bed. This allows air to flow through the support and into the powder bed, improving the efficiency of the convective drying component.

Vacuum ovens differ from convection ovens in that the heating method is accomplished strictly by conduction as there is no circulating air for convection (Mujumdar 2007). Organic vapor evolved from the powder is transported from the oven via the vacuum pump. Vacuum ovens offer the advantage drying at lower temperatures due to solvent boiling point reduction. The reduction of drying temperature is particularly advantageous for heat-sensitive actives.

Tray drying is a stagnant powder bed method; thus, drying efficiency is inversely related to bed depth (Carstensen and Zoglio 1982). Tray drying is therefore most applicable to small batch sizes where the powder can be spread thinly over the tray surfaces. For a fixed oven size and number of trays (fixed drying surface area), bed depth and drying time increase with increasing batch size (powder volume). For larger spray-dried batches, agitated bed methods such as those described below are recommended.

10.6.2.2 Fluid Bed Drying

One of the most commonly employed methods for removing residual solvent from spray-dried powder is fluid bed drying. By this method, a powder bed is acted upon by an upward flowing gas stream with a flow rate sufficient to suspend the particles without entrainment, thereby transforming the stagnant powder bed into a fluid-like state (Parikh and Mogavero 2005). The mobility imparted on the particles by the air stream allows for greater surface contact between the solids and the drying gas, thus improving the efficiency of heat and mass transfer. Consequently, drying time by this method is significantly shorter than by stagnant bed methods.

Solvent is removed from a particle by a two-step cycle consisting of: (1) surface evaporation followed by (2) diffusion of solvent from the interior to the surface of a particle (Mujumdar 2007; Wildfong et al. 2002). Evaporation of solvent from a particle surface in a fluid bed system is governed by the inlet air temperature, flow rate, solvent vapor content, and distribution in the bed (Frake et al. 1997). Heat transfer from the inlet gas to the particle over time causes residual solvent bound to the particle surface to enter the vapor state. Once in a gaseous state, residual liquid becomes entrained in the drying gas stream and is carried out to the exhaust. Solvent from the interior of the particle can then migrate to the surface by diffusion and the surface-drying process is repeated. Drying by this mechanism continues until the solvent

contained in the bulk powder bed is reduced to meet the product specifications. Intermittent loss on drying or GC measurements should be used to monitor residual solvent levels and determine the drying endpoint.

Fluidized bed drying is an efficient process for removing residual solvent from spray-dried powder. It is particularly useful for large masses of powder where tray drying is not practical. Because particle size of spray-dried powders is typically fine, fluid bed drying can be problematic with respect to powder loss in the exhaust and clogging of filters. This can usually be overcome by proper selection of filter bags and utilization of blowback to dislodge powder from the filters. Also, proper control of fluidization will limit particle entrainment in the drying gas that causes filter clogging. For cases where powder loss or filter clogging is excessive, alternative drying methods such as tumbling or agitated bed drying are recommended.

10.6.2.3 Rotary and Agitated Bed Driers

Other equipment options for removing residual solvent from spray-dried powder include agitated bed driers and rotary drum driers. Agitated bed driers utilize mechanical agitation to stir the powder bed and improve drying efficiency, as opposed to air fluidization. In a typical drier of this type, an impeller distributes the powder bed within the drying vessel to provide even product contact with the heated surfaces of the chamber. Heat transfer in these systems is therefore governed by conduction. Agitated bed driers are typically operated under vacuum to further improve drying efficiency. These driers therefore offer the benefits of vacuum oven drying with the additional advantage of improved heat conduction. An EKATO Vertical Dryer is an example of an agitated bed drier commonly used for secondary drying of spray-dried powders.

Rotary driers employ the use of a rotating heated drying chamber to constantly tumble the powder bed for enhanced heat transfer. The drum is typically equipped with baffles to evenly distribute the powder along the walls of the chamber and improve drying efficiency. These systems can be operated under vacuum or purged with heated drying gas. Several manufacturers offer rotary drier systems for various production scales.

10.7 Fluidized Spray Drying

The versatility of spray drying also encompasses its combination with other technologies. Fluidized spray drying (FSD) is the combination of fluid bed and spray drying in a single system. By the incorporation of fluid bed drying into the spray-dried system, the product emerges from the process with little to no residual solvent content, i.e., there is no need for secondary drying. This technology also enables the production of agglomerated particles with particle sizes much larger than in conventional spray drying. A picture of an agglomerated particle produced by FSD is provided in Fig. 10.7. Additionally, FSD reduces the fines content in the spray-dried

Fig. 10.7 Picture of an agglomerated particle produced by FSD. Reproduced with permission from Hovione FarmaCiencia SA

product which improves powder flowability. Finally, according to the particle agglomeration achieved by FSD, spray-dried powders with much greater densities can be achieved. This improves downstream processing efficiency by eliminating the need for a subsequent densification step, thereby enabling direct tablet compression or capsule filling (Bittorf et al. 2010).

The FSD concept was patented in 1984 for the production of agglomerated milk powder with better dissolution properties (Pisecky et al. 1984). In FSD, the solution is atomized at the top of the drying chamber in co-current configuration with the drying gas as in conventional spray drying (see Fig. 10.8); however, the drying gas exits through the top of the drying chamber. Therefore, the flow patterns inside of the drying chamber are totally different from conventional spray drying. This gas flow pattern promotes particle collisions and consequently agglomeration. After exiting the drying chamber through the top, the gas goes to the cyclone. Here, the particles are captured and re-introduced in the drying chamber. The gas stream coming from the cyclone may be introduced in a position concentric to the nozzle or tangentially to the drying chamber at a given height (Bittorf et al. 2010). This promotes more effective agglomeration because the particles coming from the cyclone collide with the droplets/wetter particles nearer the top of the chamber. In fact, all particle agglomeration takes place within the drying chamber.

As particles agglomerate and become denser, they will move down to the bottom of the drying chamber where the fluidized beds are installed. In Fig. 10.8, a schematic diagram is provided depicting the fluidized spray-drying setup with three-fluid bed driers (FB1, FB2 and FB3).

Fig. 10.8 Fluidized spray drying. Adapted from Bittorf et al. (2010)

The number of fluidizing beds may vary between equipment from one to three. Fluidizing bed one (FB1) is directly connected to the drying chamber and works as the main fluidizing chamber. It is the primary bed responsible to perform particle selection by adjustment of the velocity of the fluidizing gas. FB2 may be used to conduct a secondary drying step to further decrease the residual solvent content while FB3 may be used to cool down the product before final discharge. The passage between the fluidized beds is achieved based on differential pressures across the beds. Their temperatures are adjusted independently.

From the previous description, it is obvious that the residence time in the primary drying process for FSD is much greater compared to traditional spray drying. This enables the use of even milder drying temperatures, which is beneficial for processing of low glass transition temperature products and for increasing product density. Bittorf and coworkers reported particles up to 259 μm and densities up to 0.32 g/ml for VX-950 solid dispersion obtained by FSD (Bittorf et al. 2010).

The main limitation of FSD is the absence of laboratorial-scale or pilot-scale units that are representative of the process at larger scales. This has prevented in many instances the development of pharmaceutical products using this technology. Recently, efforts have been made to design laboratorial-scale equipment that can replicate the FSD process at commercial scale (Assunção 2011). The results were very promising and the powder produced in this laboratorial scale unit showed much better flowability than the typical spray-dried powder obtained at the same scale.

10.8 Spray Drying for Amorphous Solid Dispersion Systems

The increasing frequency at which poorly water-soluble molecules are entering drug development pipelines and the problem it poses to the pharmaceutical industry have been stated previously in this book. The value of amorphous systems with respect to overcoming intrinsic solubility limitations and improving the bioavailability of insoluble drugs is also covered in detail in this text (Chap. 3). More specifically, the value of solid dispersion systems with respect to stabilizing the amorphous form of a drug and enhancing its bioavailability is a recurring theme woven throughout the chapters. In this section, the application of spray-drying technology for the production of amorphous solid dispersions (ASDD) will be discussed in detail.

10.8.1 Solvent Evaporation Method

There are principally two approaches for producing amorphous solid dispersion systems: (1) thermal processing (see Chap. 9) and (2) solvent-based processing (Chiou and Riegelman 1971). Basic solvent processing for the production of amorphous solid dispersion systems involves dissolution of the drug and the excipient carrier(s) in a common solvent followed by rapid separation of the solids from the solvent to form, ideally, a single-phase composite. This can be accomplished in one of the two ways: (1) solvent evaporation or (2) induced precipitation by introduction of an anti-solvent (see Chap. 12). From a process and scalability perspective, the former method is the more straightforward and is thus more widely applied.

Solvent evaporation for the production of solid dispersion systems can be carried out as a batch operation by drying a solution of drug plus excipients with the use of a vacuum oven, lyophilizer, or a rotary evaporator. This is a commonly used approach in early development stages when API quantities are limited. One must be careful when employing this technique as gradual solvent evaporation can lead to drug–excipient phase separation (Curatolo et al. 2009). This can lead to false negative results with respect to homogeneity, stability, and performance of the disperse system. Also, exposure to thermal stress during this process can be significant; thus, care must be taken with this approach for thermally labile molecules. Finally, the dried solid material will typically be in the form of a film or a solid foam and thus particle properties will be irregular and possibly heterogeneous from batch to batch. Care must be taken with post-processing (milling and sieving) to ensure that the product meets the desired specifications.

The spray-drying process offers numerous advantages over batch solvent evaporation. First, spray drying is continuous and as such is a more commercially viable process. Second, atomization of the liquid feed results in rapid evaporation of the solvent from droplet surfaces and consequently rapid droplet solidification. This is particularly critical for ASDDs with regard to preventing drug–carrier phase separation that can lead to physical instability and poor product performance (Friesen et al. 2008). Third, residence time in the drying chamber is typically on the order of

seconds; thus, exposure of API to thermal stresses is minimal. Forth, spray drying is simple and easily tunable; hence, the process can be readily optimized to generate the desired particle properties with limited batch-to-batch variability. This includes dry product with particle properties amenable to direct tablet compression and/or capsule filling, yet another advantage of spray drying. Finally, spray drying can be conducted in a wide spectrum of scales, from bench to commercial scale, without dramatic changes to the process. Accordingly, spray drying is easily transferred between scales to meet the increasing drug product needs of an evolving development program. According to these attributes, spray drying and ASD technology is applicable to drugs with widely varying physiochemical properties and can be implemented at any stage in drug development.

10.8.2 Solvent Selection

The identification of a poorly water-soluble drug as a good candidate for spray drying begins during the preformulation stages. Essentially, the determinant factor is the compound's solubility and stability in organic solvents that are suitable for spray drying. A solubility screening study should be conducted to determine the solvents and co-solvent systems in which the drug has sufficient solubility to enable spray drying with reasonable solids throughput. As a rule of thumb, the drug should have solubility of at least 1–3% to consider spray drying a viable option for large-scale manufacturing. Following selection of the solvent system, stability studies of the drug in solution should be conducted to identify instability of the compound in the solvent and determine the time scale of degradation in order to establish a shelf life. Considering that in large-scale production a solution may be sitting for several hours or days before and during spray drying, stability of the drug in the solution is important.

10.8.3 Carrier Selection and Optimization

In an amorphous solid dispersion system, the carrier principally serves the following functions: (1) imparts stability onto the amorphous drug in the solid state, (2) enhances solubility and/or prolongs supersaturation in aqueous environments, and (3) dictates the primary location of drug release in the GI tract. Owing to properties such as high molecular weights, high T_g 's, water solubility, varying ionic character, and, in some cases, surface activity, polymers are almost exclusively utilized as the primary carriers for amorphous solid dispersion systems. The most commonly used polymers for ASD applications are provided in Table 10.10. Nonpolymeric additives are also frequently incorporated into carrier matrices, but typically serve secondary roles as functional adjuncts, for example, wetting agents, pore formers, moisture scavengers, densifying agents, anti-plasticizing agents, etc. Selection of optimal polymers for amorphous solid dispersion systems is discussed in detail

Table 10.10 Polymers commonly used in solid dispersions produced by batch solvent evaporation and/or spray drying: suitable organic solvents and corresponding references for use

| Common polymers | Suitable organic solvents | Selected references |
|---|--|--|
| Hypromellose Acetate Succinate (HPMCAS) | Acetone, ethyl acetate, methanol/ethanol:dichloromethane (1:1 v/v) | Tanno et al. (2004), Kennedy et al. (2008), Friesen et al. (2008), Curatolo et al. (2009) |

| Poloxamers | Acetone, most alcohols dichloromethane, ethyl acetate, methyl ethyl ketone, tetrahydrofuran | Jung et al. (1999), Wong et al. (2006) |
| Polyvinyl Acetate phthalate (PVAP) | Ethanol, methanol, acetone:ethanol (1:1 w/w), acetone:methanol (1:1 w/w), methanol:dichloromethane (1:1 w/w) | Curatolo et al. (2009) |
| Cellulose acetate phthalate (CAP) | Acetone, methyl ethyl ketone, ethyl acetate | Curatolo et al. (2009) |
| Amonio Methacrylate Copolymer | Acetone, methanol, ethanol, isopropyl alcohol, tert-butyl alcohol dichloromethane, ethyl acetate, methyl ethyl ketone, tetrahydrofuran | Jung et al. (1999) |
| Hypromellose Phthalate (HPMCP) | Acetone (with heat); ethanol:dichloromethane (1:1, 2:1), methanol: dichloromethane (1:1) | Kohri et al. (1999), Tanno et al. (2004), Engers et al. (2010), Curatolo et al. (2009), Cui et al. (2006) |
| Hydroxypropyl cellulose (HPC) | Dichloromethane, ethanol, methanol, chloroform | Curatolo et al. (2009), Cui et al. (2006) |

elsewhere in the book (Chaps. 1 and 8). Therefore, discussion of carrier selection for ASDDs in this section is kept intentionally brief.

10.8.3.1 Solubility in a Common Solvent

For amorphous spray-dried dispersions, the polymer must be soluble in a common solvent or solvent system with the drug. This is to ensure mixing of the drug and polymer at a molecular level such that a single-phase system can be achieved on drying. Although there are some cases in which amorphous systems can be successfully produced from liquid feeds in which the drug is in solution and the polymer in suspension, a complete solution is usually desired so as not to risk the formation of a less stable two-phase composite. A list of some suitable organic solvents for each commonly used polymer is provided for reference in Table 10.10.

10.8.3.2 Drug–Polymer Miscibility

Selection of the appropriate polymer for an ASDD should begin during the preformulation stages. Once a drug candidate is identified as potentially requiring formulation as an amorphous solid dispersion, efforts should begin to identify polymers that are miscible with the compound. Drug–polymer miscibility is a critical consideration during polymer selection, because in a substantial majority of cases drug–polymer miscibility is a requirement for physical stability of the noncrystalline drug.

As discussed in Chap. 2, calculation of solubility parameters can be useful for identifying good polymer candidates for ASDD systems with the drug of interest. Conversely, solubility parameters will aid in identifying polymers that have limited miscibility with the drug that should be avoided. Although solubility parameters can provide valuable insight into drug–polymer miscibility for a broad number of polymer candidates, these predictions can sometimes be misleading; therefore, empirical data is preferred.

High-throughput, material sparing screening methods for assessing drug–polymer miscibility, like those described in Chap. 8 and elsewhere in the pharmaceutical literature (Kwong et al. 2011; Moser et al. 2008a, b; Shanbhag et al. 2008), are recommended for rapidly assessing a multitude of carriers while consuming minimal API. Typically a 96-well robotic system is utilized to produce and analyze solvent cast drug–excipient films. Following evaporation of solvent, the cast films in each well are analyzed by high-throughput PXRD, polarized light microscopy, and electron microscopy for evidence of drug crystals or phase separation (Moser et al. 2008a). The rapid nature of screening allows for assessment of numerous polymers with varying drug loads. Polymers which are identified as miscible with the drug beyond the target drug loading range should then be selected for further evaluation on a larger scale.

10.8.3.3 Rapid In Vitro Screening of Carrier Excipients

As discussed in Chap. 2, various in vitro tests can be conducted to assess performance of excipient carriers for ASDD systems with respect to: solubility enhancement, prolongation of supersaturation, and finally supersaturated dissolution testing. With respect to solubility enhancement, screening studies can be conducted in which the crystalline drug is incubated under agitation with the excipient system in aqueous media for a suitable duration to establish equilibrium. The system is then centrifuged or filtered and the supernatant or filtrate is analyzed for drug concentration. Excipients can then be rank ordered with respect to drug solubility enhancement and selected accordingly for further study. Typically, polymers and surfactants are screened separately and leads from both groups are combined to evaluate potential synergies. By this method, one can quickly determine lead polymers, surfactants, and combinations thereof for small-scale spray-drying studies.

In compliment to solubility enhancement, a supersaturation assay should be performed to comparatively evaluate various polymers, surfactants, etc., with respect to prolongation of drug supersaturation. As described by Vandecruys et al., this screening protocol involves pre-dissolving the excipient(s) in aqueous media and then introducing the drug as a solution in a water-miscible organic solvent such as dimethylacetamide (Vandecruys et al. 2007). The drug will initially be highly supersaturated but will precipitate with time at varying rates depending on the drug–excipient interactions in solution. According to this rate of precipitation, a rank order for the evaluated excipients can be established.

A high-throughput screening method similar to that described above for drug–carrier miscibility determination can also be employed for rapid assessment of the dissolution performance for a vast array of compositions. According to this method, dissolution testing is conducted on the solvent cast films in each well of a 96-well plate. Filtration and analysis of drug concentration by HPLC can be automated to provide rapid results. For specific details regarding this method, the reader is referred to Shanbhag et al. (2008) and Chap. 8 of this text. According to the automated nature of the system and the number of wells per plate, numerous dissolution experiments can be conducted simultaneously. This provides opportunities for the formulation scientist to broadly screen numerous polymers, surfactants, other adjuvant excipients, and combinations thereof well beyond what is possible by manual means.

A typical high-throughput dissolution screening procedure employed for developing an ASDD formulation will first involve screening a variety of polymers at a given drug loading. Following identification of lead polymers, another plate array will be designed to investigate synergies between lead polymers and various surfactants. Next, concentrations of lead surfactants are varied to identify an optimum. Finally, with lead polymers, surfactants, and surfactant concentrations identified, the influence of drug loading for the various carrier systems can be evaluated. Ideally, at the completion of this procedure, lead polymers, surfactants, and combinations have been identified along with optimum drug loadings.

Considering the results of the solubility enhancement screening, supersaturation assay, and high-throughput dissolution screening together, the formulation scientist

will have extensive information regarding carrier compositions that yield acceptable dissolution performance. With this information, the formulation scientist can begin to design ASDD formulations and produce powder on small-scale equipment, e.g., a Buchi Nano B-90 or Buchi Mini B290 spray drier (see Table 10.3). At this point, *in vitro* dissolution screening can be performed on the actual spray-dried powder formulations. This *in vitro* testing is critical because the above test methods are only approximations of the performance of the actual ASDD system. The only means of truly evaluating the performance of various carrier systems for ASDDs is to perform dissolution testing on the actual spray-dried powder. Any unexpected results, whether positive or negative, obtained from the above-described screening methods can also be reevaluated with actual ASDD material to avoid unwarranted acceptance or rejection.

10.8.3.4 In Vitro Dissolution Testing of ASDDs

There are several options for *in vitro* dissolution testing of spray-dried powder as described in detail in Chap. 2. Selection of the appropriate dissolution test method should be made based on the quantity of material available, the properties of the drug, and the formulation components. Small-volume, material-sparing dissolution testing methods include the micro-centrifuge (Curatolo et al. 2009) and syringe/filter methods (Curatolo et al. 2009). Larger-volume methods (500–1,000 mL) typically involve the use of traditional USP Apparatus II systems (paddle method). Scaled-down versions of the paddle method (~100 mL) have also been used (Overhoff et al. 2007).

Dissolution of ASDD systems should be conducted at nonsink conditions in order to assess the extent and duration of supersaturation since these are the key metrics for predicting *in vivo* performance (Miller et al. 2008a, b). Considering that the supersaturated dissolution testing of amorphous solid dispersion systems will lead to not only free drug in solution but also a variety particulate species (Friesen et al. 2008), it is imperative to also utilize an appropriate method for separating drug in solution from solid particles. This can be accomplished by filtration or centrifugation of aliquots of the dissolution media; however, these methods are not always effective at eliminating particulates. Alternative methods for measuring free drug include passive diffusion systems employing a semi-permeable membrane and biphasic dissolution systems containing an octanol layer into which the drug partitions (Heigoldt et al. 2010; Shi et al. 2010).

The appropriate dissolution media must be selected according to the properties of the drug and the formulation. If the drug has pH-dependent solubility, a pH shift method should be employed in order to capture pH influences on dissolution/precipitation and evaluate formulation performance accordingly. Also, if the polymer is ionic, it should be soluble in at least one stage of the dissolution test, i.e., one should not test an enteric polymer-based system only in acidic media. If the drug and polymer are nonionic, a single-stage test should be sufficient. In both single-phase and multi-phase dissolution tests, selection of media should be based on

Fig. 10.9 Dissolution performance of ASDDs at 10% drug loading of “Compound 5” with various polymer carriers. Reproduced from Curatolo et al. (2009) with permission from Springer

iterative method development to achieve the desired discrimination between formulations and correlation to in vivo results.

Using small quantities of ASDD powder, in vitro dissolution testing can be conducted as described above to confirm (on a narrower group) the rank ordering of polymers, surfactants, and multi-component carriers as well as trends related to drug loading. An example of dissolution screening of ASDD powders to identify lead polymers was provided by Curatolo et al. (2009). As seen in Fig. 10.9, these authors established a rank order of various polymers by supersaturated dissolution testing of ASDD formulations by the micro-centrifuge method. Further description of this study is provided in Method Capsule 10.2. At the conclusion of this series of in vitro screening studies, the formulation scientist should arrive at a short list of lead ASDD formulations for analytical characterization and stability assessment.

10.8.4 Analytical Characterization of ASDD Formulations

Once spray-dried dispersions are produced, a battery of analytical tests should be conducted to thoroughly characterize the material. In Table 10.11, analytical tests most pertinent to ASDD systems are listed along with a description of purpose(s) and illustrating references. These tests are critical to perform during formulation screening for comprehensive analysis toward the identification of lead candidates. It is also important to perform these analyses each time a spray-dried batch is produced to ensure that it meets product specifications. Additionally, when evaluating

an ASDD product following storage at accelerated conditions, it is important to assess changes in the material by these methods. Specifically, the use of polarized light microscopy (PLM) and scanning electron microscopy (SEM) is important with respect to identifying the emergence of drug crystals as these techniques are straightforward and highly sensitive. For a more thorough summary and detailed descriptions of these techniques, the reader is referred to Chap. 2.

10.8.5 Stability of Amorphous Spray-Dried Dispersions

Stability screening of ASDD formulations is as critical to selecting lead compositions as in vitro performance. As with drug–carrier miscibility and in vitro testing, it is imperative to establish a rank order of formulations with respect to stability such that at the end of screening rank orders of all criteria can be assessed together in the selection of lead ASDD formulations. To this end, accelerated stability studies should be performed on binary ASDD systems (drug and primary carrier) at varying

drug loads between the upper limit determined from miscibility studies and the lowest practical drug loading. Once produced, the binary mixtures should be stored at accelerated conditions, e.g., 40 °C/75% RH, 50 °C, 60 °C – in open and closed containers. Samples should be pulled according to a stability schedule and physical stability should be evaluated. PXRD is the most common method for the detection of recrystallization; however, the limit of detection of this method is typically around 5% (Friesen et al. 2008). Microscopy-based methods, such as SEM and PLM, are therefore recommended for first-line detection of recrystallization as it is possible to detect the presence of drug crystals by these techniques well below the limit of detection of PXRD. An example of such a stability program is provided in Table 10.12 in which amorphous systems of VX-950 were stored at varying conditions and durations and then evaluated for the presence of crystallinity (Cui et al. 2006). It is observed that all samples were initially amorphous; however, the pure amorphous drug and the ASDD formulation with the PVP K30 carrier showed evidence of crystallization after one month at 40 °C/75% RH.

Identification of physical instability of an amorphous system by an accelerated method is not necessarily a reason to eliminate a carrier from further development, particularly if *in vitro/in vivo* performance suggests selection of that polymer. This method is simply used to rank order the physical stability of the amorphous formulations to allow identification of the optimum polymer taking into account all attributes of the system. For example, if a certain high-performing (*in vitro/in vivo*) carrier system tends to absorb moisture leading to destabilization of the amorphous

API, certain packaging configurations can be utilized to protect the drug product from moisture. In this example, accelerated stability testing serves as an early indication that packaging will be critical to product stability. Alternatively, if all other aspects of several amorphous formulations are similar yet there are significant differences in physical stability, it would be wise to focus efforts on the most stable systems.

In addition to physical stability, chromatographic analysis (HPLC) should be conducted on the accelerated stability samples to detect changes in potencies and impurity profiles with storage time. This will provide an early indication of chemical incompatibility of the drug (in a noncrystalline state) and polymer(s). This is particularly important for amorphous formulations, because excipient compatibility studies conducted during preformulation stages typically utilize the crystalline drug in a binary blend with the excipient and therefore do not adequately simulate the drug–excipient interactions in an ASDD system. If the levels of impurities are minor, or if there is an opportunity to qualify the impurities during toxicology studies, some chemical incompatibility may be manageable. However, if the formation of impurities is substantial (significantly reducing product potency) and there is no opportunity to qualify the impurities, then such chemical instability would be an eliminating factor for the carrier.

By accelerated stability programs, polymers can be rank ordered with respect to physical and chemical stability of the amorphous drug. As key adjuvant excipients are identified by *in vitro* dissolution screening, SDD compositions containing these excipients should also be subjected to accelerated stability studies. Those systems with unmanageable physical and chemical instability should be eliminated from consideration.

10.8.6 Pharmacokinetic Evaluation

At the culmination of spray-dried dispersion development, an animal PK study should be conducted to select the final ASDD formulation(s) from the leads. When developing a formulation for toxicology studies, PK assessment should be conducted in both animal species selected for the toxicology studies. In this case, the best performing formulation is directly selected. In the case of clinical and market formulation development, animal PK assessment of the lead ASDD intermediates is done to reduce the leads to a number manageable for prototype dosage form development. This will include process development and scaleup which may result in further reduction of intermediate formulations based on manufacturability. Ultimately, the prototypes will be evaluated again in animal PK studies before the selection of clinical formulation(s). For entry into humans, the best performer from this final animal study will proceed into clinical study. For phase II/market formulations, this final animal PK study will be used to narrow the candidates to a suitable number to test in a human bioavailability or bioequivalence study, with the final clinical/market formulation being selected based on these results.

10.8.7 *Preclinical Considerations*

Drug insolubility can be particularly challenging in the preclinical phases of development. Specifically, achieving exposures in animal models that are sufficient to establish adequate safety margins over the predicted efficacious dose can be difficult with poorly soluble compounds. Poor solubility limits not only exposure but dose linearity as well. Dose linearity tends to be poor for insoluble compounds as plateauing exposure is often seen during dose escalation and prior to achieving the desired exposure. Reducing the particle size of the crystalline API by micronizing, wet milling, or nano-milling can improve exposures but are often not sufficient to achieve the target exposures for high-dose insoluble molecules due to inherent solubility limitations of the crystalline form. Solution formulations are another often-employed approach that can yield improved exposures and dose linearity over the crystalline drug; however, poor drug solubility in suitable vehicles and vehicle dose restrictions often limit the amount of compound that can be administered with these formulations.

ASDD systems offer obvious advantages over crystalline suspension and solution formulation approaches. First, by converting the API to an amorphous form, the inherent solubility limitations associated with the crystalline API are eliminated. Second, if properly designed, the solid dispersion formulation can be easily constituted in standard aqueous vehicles and can remain amorphous for several hours to enable a sufficient time window for dosing. Therefore, amorphous solid dispersions offer the solubility benefits of a solution formulation without the need for nonaqueous vehicles that can limit dosing volumes. Additionally, ASDDs are oftentimes found to provide improved exposure and dose linearity over solution formulations. This is likely due to the intimate association between the drug and the excipient carrier which delays precipitation with respect to solution formulations which can be less efficient in keeping the drug in solution when mixed with GI fluids.

An example of improved exposure and dose linearity for an ASDD-based toxicology formulation is described in an article by Kwong et al. (2011). In this example, the researchers developed an ASDD formulation with an HPMCAS-HF carrier for a poorly water-soluble molecule, “compound 3.” The powder was dosed as a suspension from an aqueous vehicle containing 0.5% methylcellulose and sodium lauryl sulfate (SLS). The dose proportionality comparison of this formulation between suspensions of the pure crystalline and amorphous drug is shown in Fig. 10.10. From these results, it is observed that the ASDD formulation provided far superior exposure and dose linearity as compared to the suspension formulations.

Selecting the appropriate carrier for an amorphous spray-dried dispersion intended for toxicology studies is critical not only to achieve the maximum drug exposure and dose linearity but also to ensure that the ASDD formulation remains amorphous in the vehicle for a sufficient duration to facilitate dosing of multiple animals from the same suspension lot. For this purpose, ionic polymers tend to be the best carriers. There are numerous articles in the literature which demonstrate the benefit of anionic polymers for intestinal targeting of supersaturation to improve oral absorption of insoluble compounds (Curatolo et al. 2009; Friesen et al. 2008;

Fig. 10.10 Dose proportionality of crystalline compound 3 in 10% Tween (filled triangle); amorphous form in 0.5% Methocel/0.24% SDS (filled square); solid dispersion at 50% drug loading in HPMCAS-HF in suspension (filled circle) from 10 mpk to 750 mpk dosed at 5 ml/kg in Sprague Dawley rats ($n=4$). Kennedy et al. 2008; Kohri et al. 1999; Miller et al. 2008a). The additional benefit of these polymers for toxicology formulations is that they are insoluble in aqueous buffers of $\text{pH} < 5$. By properly adjusting the pH of the vehicle, the solid dispersion can remain amorphous for several hours to facilitate dosing.

Suspension stability of an ASDD-based toxicology formulation as a function of vehicle pH was demonstrated in articles by Moser and coworkers (Moser et al. 2008a, b). In this study, the authors describe the development of an ASDD formulation with an HPMCAS-HF carrier in support of high-dose preclinical safety studies of “compound A.” This formulation was found to yield a tenfold increase in exposure over a crystalline formulation in dogs and thus enabled dose escalation to the desired exposures. As part of the toxicology formulation development process, these authors investigated the influence of vehicle pH on the physical stability of the ASDD formulation in suspension. The results of this study for low concentration suspensions (1 mg/mL) in deionized (DI) water and pH 4.0 acetate buffer are shown in Fig. 10.11. These results clearly demonstrate the influence of vehicle pH on the physical stability of the ASDD formulation. Recrystallization of compound A is evident only after one hour in DI water, whereas no appearance of crystals is seen in acetate buffer for at least four hours. This example thus illustrates the importance of utilizing a buffered vehicle of pH below the onset of dissolution of the carrier polymer to ensure physical stability of the ASDD system for a duration sufficient for study dosing.

As with any amorphous solid dispersion, optimizing drug loading of the formulation is critical. It is particularly important for toxicology formulations not only to

Fig. 10.11 XRPD spectra of solids pulled from suspension (dried at R.T., vacuum) in both DI water and pH=4 buffer, spray-dried dispersion (control), and crystalline API. Order from top to bottom: DI water (4, 2, 1 h), pH=4 acetate buffer (4, 2, 1 h), spray-dried powder, crystalline API. Reproduced from Moser et al. (2008b) with permission from Russell Publishing, LLC

achieve the required drug exposures but also to ensure suitable drug loading and amorphous stability in suspension. The upper limit of solids loading of ASDD powder in aqueous vehicles is typically in the range of 15–30% (w/v). As solids loading is increased, the suspension becomes increasingly viscous up to a point where dosing via gavage is prohibitively difficult. Given this limitation, it is important to maximize drug loading in the solid dispersion system to achieve acceptable drug concentrations in the suspension.

For example, a suspension in which maximum viscosity is achieved at 20% (w/w) solids loading with an ASDD containing 10% active results in a maximum suspension concentration of only 20 mg API/mL, whereas a solid dispersion containing 30% drug loading yields a maximum of 60 mg API/mL suspension, thus enabling a threefold higher dose per volume. Achieving adequate drug loading in the ASDD is essential to achieving the target exposures for molecules requiring highly elevated exposures for toxicity assessment. However, drug loading must be balanced against suspension stability, as higher drug loading tends to result in faster recrystallization in the vehicle because there is less excipient to protect the amorphous drug. Experimentation is required to determine the maximum drug loading that can be maintained amorphous in suspension for a suitable dosing time interval.

Spray drying as a formulation technology is also advantageous for toxicology formulations with respect to the physical properties of the powder product. Controlling particle size is important to ensuring that a formulation can be administered via gavage needle of reasonable gauge for rat dosing. Since it is straightforward to produce spray-dried dispersions with a mean particle diameter of less than 100 μm , spray drying is an ideal process for producing particles that are easily delivered by standard animal dosing practices. It is also important that powders for constitution utilized for toxicology purposes wet and suspend well in the delivery vehicle. In this regard, spray-dried powder is ideal in that it is typically high surface area and low bulk density. Therefore, with appropriate carrier selection, wettability and suspendability of spray-dried powder is typically very good. Thus, spray drying produces easily constitutable powders that yield homogenous suspensions that are easily and accurately dosed to all animal species.

Spray-dried solid dispersions also offer processing advantages during pre-clinical phases of development. First, spray drying on very small and very large scales can be accomplished rather easily. Therefore, it is straightforward to produce the drug product as it progresses through the various phases of clinical candidate selection: from PK studies, to dose range-finding studies, to multi-week GLP toxicology studies. Often the transition between these phases can be rather fast and API may only become available just prior to the study start. Hence, there is little time and drug available for extensive process development and scaleup. The concept of an ASDD can be proven on a very small scale, using a Buchi Nano Spray Dryer B-90 system for example, and this powder can be used to supply initial animal PK studies. At a small scale, optimizing the spray-drying process involves a simple design of experiments study to identify acceptable process parameters. With the basic process parameters established, step-wise scaleup of the spray-drying process to meet the increasing needs of a progressing safety assessment program is straightforward. Hence, the ease in transitioning between different scales for the production of ASDD formulations makes it an ideal process for the manufacture of formulations for preclinical safety studies at all development stages.

In summary, the advantages of spray-dried dispersions to preclinical development are manifold. First, aptly formulated ASDDs yield a more bioavailable form of the drug that is also physically stable in suspension. Second, spray-dried powder is ideal for constitution in aqueous vehicles and forms a homogenous suspension which can be easily and accurately dosed by gavage. Finally, the spray-drying process can be scaled up quickly to accommodate all stages of toxicology assessment: from initial animal PK studies requiring only a few grams of drug product to multi-week GLP studies requiring tens of kilos.

10.8.8 Clinical Considerations

There are a few key benefits to utilizing an ASDD formulation strategy for a poorly water-soluble molecule for entry into and progression through clinical development,

aside from the obvious enhancement of oral bioavailability. Paramount among these benefits is that insoluble molecules will typically require a solubility enhanced formulation for preclinical safety studies as well for safety and efficacy assessment in humans. Therefore, an optimized ASDD formulation used in preclinical safety studies can often be directly utilized in clinical formulation development. An obvious benefit to this situation is reduced development time. Another key benefit relates to the safety assessment of the ASDD formulation. By using the same or similar ASDD formulation in clinical studies as was used preclinical safety evaluation, any impurities unique to the ASDD formulation will have been previously qualified. Moreover, safety of the carrier formulation will also have been established. Since ASDD formulations often include excipient components for which there is no safety precedent at the delivered amount, the latter benefit is an important one.

ASDD formulations also offer advantages to clinical studies with respect to their applicability to various final dosage forms, such as powder for constitution, powder in a capsule, tablets, etc. This flexibility provides formulation scientists various product options to choose from at each stage of clinical development while keeping the critical component of the formulation constant. This allows for quick reaction to the development program's changing drug product needs. For instance, to achieve rapid entry into clinical studies, a simple powder in a bottle concept can be employed to minimize product delivery time to the clinic while providing dosing flexibility for ascending dose studies. As the program moves into small patient studies, a portable easy-to-dose formulation may be required, e.g., for take-home studies. In this case, a powder in a capsule formulation can be rapidly developed from the ASDD formulation. Finally, as the program moves into phase IIb, a close-to-market tablet formulation could be required. This tablet dosage form could also be developed in a relatively short period from the ASDD formulation. Keeping the critical component formulation constant throughout the various phases of development ensures similar PK performance of the various delivery systems, thereby reducing risk of formulation-related issues in late-phase development. A more detailed discussion of key considerations for converting ASDD intermediates into these final dosage forms will be described in detail in the following section.

10.8.9 Final Dosage Form Development

After the formulation and processes have been developed, efforts are then focused on converting ASDD intermediates into final dosage forms. In this section, downstream processing of spray-dried intermediates for the facilitation of final dosage form manufacturing is discussed. Common issues encountered when post-processing spray-dried powders will be reviewed along with methods for overcoming these problems. Then, final dosage form development is discussed with focus on the most common systems along with strategies for utilization according to the stage of development.

Fig. 10.12 Morphologies of spray-dried powder. Reproduced from Curatolo et al. (2009) and Friesen et al. (2008) with permission from Springer and the American Chemical Society, respectively

Table 10.13 Example properties of a bulk spray-dried dispersion. Adapted from Crew et al. (2007)

| Bulk properties (After secondary drying) | Tray dried @ 40 °C |
|--|--------------------|
| Bulk specific volume (g/cm ³) | 0.2 |
| Tapped specific volume (g/cm ³) | 0.313 |
| Hausner ratio | 1.56 |
| Mean particle diameter (μm) | 80 |
| D ₁₀ , D ₅₀ , D ₉₀ * (μm) | 25, 73, 143 |
| Span (D ₉₀ -D ₁₀)/D ₅₀ | 1.60 |
| Residual Acetone (Before Secondary Drying) | 3.0% |

10.8.9.1 Powder Densification

The particle morphology of spray-dried dispersions, as illustrated by Fig. 10.12, tends to resemble a hollow or shriveled sphere structures. This particle morphology leads to high surface area which is advantageous for dissolution enhancement; however, it also results in low bulk density of the spray-dried powder which can be problematic with respect to dosage form production.

The bulk density of spray-dried powder can vary significantly, depending on the scale of manufacturing, formulation, process parameters, and nozzle type. For typical amorphous solid dispersions, bulk densities can range from <0.1 g/cm³ up to about 0.4 g/cm³. Bulk densities of greater than 0.4 g/cm³ are rarely achieved by conventional spray drying alone. Typically, bulk densities of spray-dried powders fall in the range of 0.1–0.35 g/cm³. An example of the typical properties of spray-dried dispersions is provided in Table 10.13. It is typically the case that the powder must be further densified in order to enable capsule filling or tablet compression. Density is more critical with high-dose compounds where a large amount of spray-dried powder will be loaded into the final dosage form.

The two primary options for downstream densification of spray-dried powder are: (1) dry granulation and (2) wet granulation. As discussed previously, FSD is

another option for improving the density of spray-dried product and is particularly attractive because densification is achieved concurrently with the spray-drying process. However, FSD has only just recently found application in the pharmaceutical industry and has the restriction of limited small-scale equipment availability. Hence, traditional spray drying is of primary interest and secondary powder densification is typically a requirement. In this section, the use of dry and wet granulation for the densification of ASDD powder is briefly reviewed.

Dry granulation is a process of agglomerating powders by the application of high pressure. The pharmaceutically relevant dry granulation processes include slugging and roller compaction. Owing to greater throughput, more precise process control, and minimal need for lubricants, roller compaction has emerged in recent years as the preferred dry granulation process in the pharmaceutical industry (Kleinebudde 2004). Roller compaction is ideal for densifying ASDDs because the process does not require liquid that could destabilize the amorphous material. Additionally, many spray-dried powders have manageable flow properties, tend not to be tacky, and bond well under pressure making them particularly amenable to the roller compaction process.

Roller compaction with ASDDs can be accomplished without the inclusion of additional excipients; however, to improve processing and granulate performance typically lubricant(s), disintegrant(s) and filler(s) will be required. Following roller compaction, the densified ribbons are milled to form the granulate product. Ideally, this granulate will have a bulk density of greater than 0.3 g/cm^3 to facilitate capsule filling or tablet compression.

Dry granulation in itself is a complex science; a detailed discussion of the process is beyond the scope of this chapter. This section is included simply to make the reader aware of the options for densifying spray-dried powders to enable final dosage form production. The reader is referred to Kleinebudde (2004) and Miller (2010) for detailed discussions on roller compaction technology.

In contrast to dry granulation which can be applied to most ASDDs, wet granulation can only be applied to amorphous systems which are not sensitive to the granulation fluid. If the drug and/or polymer has solubility in the granulation liquid, the properties of the amorphous dispersion can be disrupted leading to recrystallization of the drug. An example of a scenario in which wet granulation would be an option is one where the amorphous dispersion is stabilized with an ionic polymer such as HPMCAS, HPMCP, methacrylic acid copolymer, and amonio methacrylate copolymer; the granulation fluid is of a pH at which the polymer is not soluble. Even in this scenario, the drug must be highly stable in the dispersion for wet granulation to be viable. As a precursor experiment to performing wet granulation, it is recommended to suspend the spray-dried material in the granulation fluid and monitor the morphology of the system periodically by a suitable analytical technique to determine the onset of drug crystallization. If the amorphous system remains unchanged for several hours in suspension, it is a good indication that the spray-dried powder will remain unchanged by wet granulation. Nevertheless, extensive process development and evaluation is recommended at every scale to ensure that wet granulation does not alter the properties of the ASDD.

Wet granulation of ASDDs can be conducted in a similar manner to traditional wet-granulation processes, either by low-shear, high-shear, or fluid-bed granulation techniques. As mentioned previously, it is important that the drug and the carrier system be insoluble in the granulation liquid to prevent alterations of ASDD properties. To achieve the desired granulate properties, additional excipients may be required, such as binder(s), disintegrant(s), and filler(s). As with any wet-granulation process, the granulate will need to be dried to remove excess moisture. This can be achieved by traditional drying methods as described previously. The granulate yielded from this process will ideally have a bulk density in excess of 0.3 g/cm^3 to facilitate capsule filling or tablet compression.

The amorphous nature of ASDDs coupled with the high surface area of the powders can lead to unusual responses to wet granulation. Significantly more granulation fluid may be required than with a traditional granulation to achieve the desired granulate. Also, uneven binder distribution owing to inadequate agitation of the powder bed can lead to the rapid formation large agglomerates. Higher impeller speeds and lower spray rates are therefore recommended at the start of granulation to facilitate homogenous granule formation. Because of these challenges, the reader is encouraged to employ dry granulation methods for densification whenever possible. If wet granulation is selected, the formulations scientist should endeavor to thoroughly characterize the process at lab scales before utilizing for larger-scale drug product supply.

10.8.9.2 Powder in a Bottle Formulations

As discussed previously, ASDDs offer many unique benefits as drug product for pre-clinical safety studies. Without extensive (or any) additional downstream processing, ASDD formulations can be used directly in animal toxicology studies. Pre-weighed powder filled into an appropriate container can simply be constituted with the addition of the delivery vehicle, adequately mixed and then dosed. In this context, an ASDD powder in a bottle concept is ideal.

Similarly, this concept can be employed for early clinical studies as well. The ASDD powder can be pre-weighed in individual containers which can be combined with a specified volume of a suitable liquid by shaking to create a homogenous suspension ready for administration. Alternatively, the ASDD powder can be supplied in bulk to the dosing site to be weighed by the attending pharmacist and pre-suspended in a suitable liquid prior to administration. This approach offers significant benefits with respect to reducing time and resources spent on drug product development and manufacturing. Additionally, it allows for flexibility in dosing which can be beneficial in phase I ascending dose studies.

10.8.9.3 Powder in Capsule Formulations

To reiterate, in most instances, particularly for high-dose drugs, the ASDD must be densified by an appropriate granulation method to enable efficient filling of the

required dose in a capsule of reasonable size. A standard size 1 capsule has a volume capacity of 0.5 ml. Assuming a density of 0.2 g/mL for typical bulk spray-dried powder, a size 1 capsule can hold a maximum of 100 mg of total powder. If a solid dispersion formulation contains only 30% drug, the maximum capsule dose strength achievable is 30 mg. On the other hand, if by granulation the density of the ASDD powder is increased to 0.6 g/ml, then the theoretical maximum dose strength attainable in a size 1 capsule is a more reasonable 90 mg. It is then understood that for high-dose applications and/or limitations on the number of capsules per dose administration, densification of ASDD powder is required for capsule production. Additionally, increasing the density of the spray-dried powder will significantly improve flow, thereby enhancing the efficiency of the capsule-filling process.

Another issue to consider regarding capsule filling with ASDDs is plug formation on dissolution. Plug formation in this context refers to the phenomenon in which the powder content of a capsule does not disperse following dissolution of the capsule shell. Rather, the powder is held together presumably by hydrophobic interactions to form a loose solid mass or plug. These plugs typically erode slowly in aqueous environments, thereby significantly retarding the release of the drug. It has been explained that slow dissolution of similar plugs stems from faster dissolution of the hydrophilic carrier at the surface of the plug leading to the formation of a hydrophobic drug-rich layer which acts as a barrier to drug release (Serajuddin et al. 1988).

To promote dispersion of capsule contents following dissolution of the shell, it is recommended that the ASDD granulate be blended with surfactants (Kennedy et al. 2008), wetting agents, soluble fillers, insoluble fillers, disintegrants, etc. The addition of these external excipients promotes wetting, acts as a stearic barrier to hydrophobic interaction or gel formation, and physically pushes adjacent particles away, thus acting synergistically to facilitate dispersion of the powder from the capsule shell. The result is an immediate release, as opposed to an undesired sustained release capsule dosage form.

10.8.9.4 Tablet Formulations

Similar to capsules, powder density is also a critical factor for tablet compression to improve flow and ensure that the powder mass corresponding to the required drug dose can easily fit inside the die cavity. Densification of the ASDD by the appropriate granulation method is required to enable tablet compression in most cases. As with most granulations, external excipients are required to facilitate compression and to achieve the desired tablet properties. Fillers, disintegrants, flow aids, and lubricants will likely be required to ensure acceptable manufacturability, tablet hardness, friability, and to achieve the desired performance with regard to disintegration and dissolution.

For products where the ASDD is the principal component of the final dosage form, e.g., greater than 50% w/w, carrier selection can dictate tablet performance with respect to disintegration and dissolution. Polymers which function as binders and/or gelling agents – such as hypromellose, povidone, and copovidone – tend to

produce nondisintegrating tablets when external filler is limited by dosage form size. For example, Kaletra and Norvir tablets are principally composed of amorphous solid dispersions (<20% drug loading) in copovidone (Berndl et al. 2008). With low drug loading in the solid dispersion and drug doses of 250 mg and 100 mg for Kaletra and Norvir, respectively, there is limited space in the formulations for external fillers to enhance disintegration while maintaining a reasonable dosage form size. As a result, both tablets are eroding systems. For many drugs, steady drug release from the tablet surface over the course of GI transit is suitable. However, in some cases, site-specific absorption in the duodenum for example, immediate release is required to maximize oral absorption. In these cases, a disintegrating tablet is usually required and therefore the previously mentioned polymers are not suitable as carriers for the solid dispersion. In these cases, anionic polymers such as HPMCAS, HPMCP, and methacrylic acid copolymers tend to be better carriers. In summary, carrier polymer selection for the ASDD can have a significant influence on final dosage form performance. Consideration should be given to this issue at the early stages of amorphous solid dispersion development.

10.8.10 Examples from the Pharmaceutical Literature

In the previous sections, an overview of the spray-drying process, the development of an ASDD formulation, and final dosage form design and production has been discussed. In the following sections, examples from both the pharmaceutical literature and industry illustrating the use of spray-drying technology for enhancement of dissolution properties, oral bioavailability, and therapeutic efficacy of poorly water-soluble drugs will be reviewed.

10.8.10.1 Various Compounds with HPMCAS

Some of the most comprehensive research conducted to date on ASDD systems resulted from an extensive collaboration between Pfizer Inc. and Bend Research Inc. During this collaboration, in-depth investigations were conducted on all aspects of amorphous spray-dried dispersions, including formulation design, solid-state characterization, understanding physical stability, in vitro/in vivo performance assessment, and spray-drying process design. This work involved a vast number of compounds with more than 100 different drugs formulated as SDDs and tested in animal models and 21 different drugs formulated as SDDs and tested in humans (Friesen et al. 2008). By investigating amorphous spray-dried dispersion systems with such a large number of compounds, these researchers were able to identify general trends for amorphous dispersion systems with regard to identifying optimal polymer carriers, determining optimal drug loading with regard to performance and stability as a function of key physicochemical properties, properties of amorphous dispersions in supersaturated aqueous media, and correlating in vitro and in vivo performance.

Comprehensive research articles summarizing this work were published by Friesen et al. (2008) and Curatolo et al. (2009) presenting several example molecules to illustrate key concepts.

The article by Friesen et al. (2008) thoroughly describes the attributes of HPMCAS that makes it a superior carrier for ASDD systems and provides various examples demonstrating its benefits (Friesen et al. 2008). The specific properties of the polymer identified as being amenable to amorphous spray-dried dispersions are as follows:

1. High T_g in the unionized state reducing drug mobility and enhancing physical stability of the system. Also, the hydrophobicity of the polymer in the unionized state prevents absorption of ambient moisture, further improving physical stability.
2. Soluble in volatile organic solvents, e.g., acetone and methanol, making it amenable to spray drying.
3. The formation of small stable colloids in aqueous media above pH 5 as a result of polymer ionization resulting in greater drug available for absorption in the intestinal tract.
4. Greater interactions with insoluble molecules in aqueous media resulting from the amphiphilic nature of the polymer that produces greater apparent solubilities and maintenance of supersaturation.

The article demonstrates the formation of XRD amorphous spray-dried HPMCAS systems for various compounds and discusses the use of DSC to further characterize these systems as being single phase (single T_g). Also, described is the use of calculations based on Flory-Huggins theory in combination with experimental data for the construction of phase diagrams for amorphous systems with HPMCAS. These diagrams aid in the understanding of the dispersed state of the drug in the polymer and provide valuable insight into the physical stability of the system. Accelerated stability studies are also described to aid in the prediction of long-term physical stability. Examples of systems showing physical stability at ambient conditions on the order of years is presented.

Solution properties of amorphous spray-dried dispersions are discussed at length with emphasis on distinguishing free drug from particulates and further delineating the particulate species. It is contended that understanding solution behavior of ASDDs is critical to distinguishing between formulations in vitro and predicting in vivo performance. Vastly improved dissolution performance with amorphous HPMCAS spray-dried dispersions over crystalline or neat amorphous API is exemplified with a number of molecules. This includes enhancement of dissolution rate as well as extent and duration of supersaturation. Most importantly, significant enhancement of exposure in humans with HPMCAS spray-dried dispersions is demonstrated for two compounds, as shown in Fig. 10.13.

Similar to the article by Friesen and coworkers, Curatolo et al. (2009) demonstrate the benefits of HPMCAS ASDDs to the formulation of insoluble drugs, using examples of various compounds to illustrate key aspects. In this article, significant discussion is done on screening of precipitation inhibitors and data are presented

Fig. 10.13 Comparison of human in vivo exposure for crystalline drug (or crystalline drug in gelatin capsule) and SDDs: (a) 25 wt. % compound 1/HPMCAS-M SDD (dosed at 30 mg fasted) and (b) 25 wt. % compound 3/HPMCAS-M SDD (dosed at 300 mg fasted). Fig. 10.14 Effect of drug loading on dissolution performance of ASDDs made with compound 3 and HPMCAS-MF. Reproduced from Curatolo et al. (2009) with permission from Springer

demonstrating the superiority of HPMCAS in this capacity. The superior performance of the polymer in this regard stems from the attributes mentioned earlier – specifically, the ionizable and amphiphilic nature of the polymer. Also, shown is an example demonstrating the effect of drug loading on dissolution performance of ASDDs. Shown in Fig. 10.14, these results clearly demonstrate the reduction of drug in solution resulting from increased drug loading in the formulation. Finally, the authors present human pharmacokinetic data demonstrating greater than sixfold increase in exposure of “compound 3” versus the crystalline drug (Table 10.14).

Table 10.14 Compound 3 pharmacokinetics in fasted humans after dosing a 25% compound 3:HPMCAS-MF spray-dried dispersion ($n=4$). Adapted from Curatolo et al. (2009)

| Formulation | Dose (mg) | C_{\max} ($\mu\text{g/mL}$) | T_{\max} (h) | AUC_{0-24} ($\mu\text{g}^*\text{h/mL}$) |
|--------------------------------|-----------|---------------------------------|----------------|--|
| SDD suspension | 300 | 8.4 ± 1.1 | 2.5 ± 0.6 | 46 ± 7.6 |
| Crystalline Drug in Suspension | 300 | 1.3 ± 0.3 | 2.3 ± 1.3 | 7.4 ± 3.3 |

With this example, this article also demonstrates the benefit of spray-dried amorphous dispersions, particularly those containing HPMCAS, to the formulation of poorly water-soluble drugs.

10.8.10.2 Simvastatin with Povidone

In a study published by Ambike et al., the authors demonstrated the use of spray drying to produce amorphous compositions of simvastatin (SIM), a cholesterol lowering agent (Ambike et al. 2005). These authors found that by co-spray-drying SIM with colloidal silica (Aerosil 200) and polyvinylpyrrolidone (PVP K30), the amorphous form of the low T_g ($\sim 35^\circ\text{C}$) compound could be maintained for at least three months when stored at 40°C and 75% relative humidity. The stability of amorphous SIM at accelerated storage conditions was attributed to decreased molecular mobility of the amorphous drug resulting from the anti-plasticizing effect of the polymer (composition $T_g = 115^\circ\text{C}$) as well as hydrogen bonding between SIM and PVP. The presence of colloidal silica also improved stability by acting as a moisture scavenger to prevent disruption of drug–polymer hydrogen bonding. Spray drying is key to these drug–excipient interactions because the process is crucial to the formation of a molecularly disperse system. In such a system the drug has greater opportunity to interact with the polymer, thereby decreasing drug–drug interactions and, consequently, the likelihood for SIM recrystallization.

With respect to performance enhancement, a fivefold increase in saturation solubility of SIM as well as a substantial increase in the rate and extent of SIM dissolution was achieved from an ASDD containing SIM, Aerosil 200, and PVP in a 1:2:2 (w/w/w) ratio. An in vivo study in rats revealed that the more soluble spray-dried SIM formulation performed substantially better than pure SIM with respect to the lowering of total cholesterol and triglyceride levels while increasing HDL cholesterol (Fig. 10.15). This example therefore demonstrates the use of spray drying to improve the solubility and consequently the efficacy of a cholesterol lower agent.

10.8.10.3 Protease Inhibitor with Eudragit L100-55

In a study published by De Jaeghere et al., amorphous formulation technologies were utilized to improve the bioavailability of a poorly water-soluble ($0.12 \mu\text{g/ml}$) HIV-1 protease inhibitor known as CGP 70726 (De Jaeghere et al. 2000). Amorphous microparticles and nanoparticles of the API ($\sim 20\%$ w/w) with the stabilizing

| Nanoparticles | 0.86 ± 0.21 | 1 | $2.00 \pm 0.50^*$ |
| Microparticles | 0.88 ± 0.33 | 2 | 4.40 ± 1.38 |

^aStatistically different (Student test, $P < 0.01$).

polymer, Eudragit L100-55, were produced by spray drying and an emulsion–diffusion method, respectively. The spray-dried microparticles were produced by spray drying from a methanol solution using a Buchi Model 190 spray drier. Further details regarding the method are provided in Method Capsule 10.1.

Both the spray-dried and nanoparticle formulations showed a substantial improvement in the oral absorption of CGP 70726 in dogs over the pure drug which did not generate quantifiable blood plasma levels (Table 10.15). The authors attributed the improvement in bioavailability to rapid dissolution of the amorphous API from the high-surface-area particles that was specifically targeted to the primary site of absorption by the use of a carrier polymer with pH-dependent solubility. Interestingly, despite having a substantially greater mean particle diameter (9.7 μm versus 286 nm), the spray-dried microparticles produced greater mean C_{\max} and AUC values when orally administered to dogs in both the fed and fasted states. Owing to statistical insignificance, the authors offered no explanation as to the difference. This result indicates that microparticles produced by spray drying can provide equivalent, if not greater, improvements in the oral absorption of poorly

water-soluble drugs than nanoparticles produced by seemingly more sophisticated particle engineering methodologies. When also considering the relative simplicity and proven scalability of the spray-drying process, it is clearly a much more viable technology for the production of amorphous formulations in most cases.

10.8.10.4 Ternary Systems of Itraconazole, Copovidone, and a Surfactant

Spray-dried amorphous dispersions of a poorly soluble antifungal drug, itraconazole (ITZ), with copovidone were described in articles by Janssens et al. (2008a, b). Copovidone was determined to be an effective carrier polymer for ITZ with regard to miscibility and enablement of molecular dispersions with high drug loading. As is common to most solid dispersion systems, it was found that increasing drug loading reduced the rate and extent of dissolution. To overcome this issue, a surfactant, Inutec SP1, was incorporated into the formulation and ternary solid dispersions were produced by spray drying (Janssens et al. 2008a). The addition of the surfactant was found to improve the dissolution properties of the high drug loading solid dispersions. However, ITZ and Inutec SP1 were determined to be sparingly miscible, and thus a crystalline ITZ phase was observed in compositions with high drug loading and surfactant content. It was therefore necessary to reduce drug loading and optimize the polymer-to-surfactant ratio in the carrier to yield a single-phase dispersion. Ultimately, the optimum balance of drug loading and surfactant content was established and a high-drug-loading solid dispersion with improved dissolution properties was achieved.

This paper by Janssens et al. illustrates some key issues regarding formulation of ASDDs: first, the critical aspect of selecting a polymer in which the drug has adequate miscibility to achieve the desired drug loading; second, the negative impact of increasing drug loading on the dissolution properties of the system; third, the benefit of incorporating a surfactant into a high drug load system with regard to enhancing wettability of the system, increasing drug solubility, and ultimately improving dissolution performance; and finally, optimizing drug loading and balancing carrier composition to achieve a single-phase, stable amorphous dispersion. Each of these aspects should be carefully considered when formulating an amorphous spray-dried dispersion with high drug loading.

10.8.10.5 AMG-517 with HPMCAS and HPMC

AMG-517 is a VR1 antagonist indicated for the treatment of acute and chronic pain (Kennedy et al. 2008). The free base form of the drug is poorly soluble in aqueous media, having an inherent solubility of $<7.0 \mu\text{g/mL}$ in the physiologically relevant pH range. To overcome the solubility limitations of AMG-517, the authors investigated the application of ASDD technology toward the end of developing a solid dosage form with adequate bioavailability. Specifically, the authors investigated HPMCAS-MF and HPMC-E5 as carriers in the ASDD formulations. A list of the spray-dried formulations with corresponding properties is provided in Table 10.16.

Dissolution screening of the four solid dispersion formulations was conducted at supersaturated conditions in pH 6.8 phosphate buffer compared to the micronized AMG-517 free base as a control. The results revealed a two- to fivefold increase in drug concentration with the solid dispersion formulations compared to the crystalline drug. Also, the HPMCAS-MF formulations exhibited superior dissolution performance over the HPMC formulations, and the 15% drug loading compositions performed better than the 50% loading counterparts. It was noticed during these dissolution studies that wetting of the solid dispersion powder was poor, resulting in gel formation and poor dispersion in the media. The authors resolved this issue by blending the ASDD powder with a surfactant, sodium dodecyl sulfate (SDS), at a concentration of 5% by weight. The result was a 12-fold increase in dissolution over the powder not containing surfactant.

In vivo performance of the AMG-517:HPMCAS-MF (15:85) ASDD blended with SDS dosed in a capsule was evaluated in cynomolgus monkeys against an "OraPlus" crystalline suspension form of the drug which produced the greatest exposures in preclinical studies. The results of this PK study are provided in Table 10.17. From this study, the exposure of AMG-517 from the SDD capsule was found to be 163% of that provided by the OraPlus suspension formulation. Therefore, the SDD capsule oral dosage form was selected for use in clinical studies.

For additional information regarding the methods used in the development of the HPMCAS-MF ASDD system, see Method Capsule 10.3.

This example not only illustrates, once again, the superiority of HPMCAS as a carrier for SDD formulations but also describes the common wetting problem with these systems. The hydrophobic nature of HPMCAS and similar polymers in the unionized state often leads to gel formation in acidic aqueous media. In capsules, this phenomenon can lead to plug formation in which the powder does not disperse from the capsule shell. As in this study, the result is a substantial reduction in the dissolution of the API from the ASDD system. Externally blending the ASDD with surfactants such as SDS or docusate sodium, as was done in this study, is a highly effective solution. Incorporating surfactants directly into the ASDD formulation is another strategy often employed. Ultimately, this article demonstrates the use of ASDD technology, with proper downstream processing, for improving the exposure of a poorly water-soluble molecule and enabling development of a highly bioavailable solid oral dosage form for use in clinical studies.

10.8.10.6 Albendazole with HPMCP and HPMC

As demonstrated by previous examples, anionic polymers can be particularly effective as carriers in ASDD systems owing to their ability to target supersaturation to the neutral pH environment of the intestinal tract and maintain elevated free drug concentrations for the duration of intestinal transit. An early example of this concept was provided in a paper by Kohri et al. (1999) in which the authors demonstrated the use of a dual polymer carrier system consisting of HPMCP and HPMC for improved oral delivery of albendazole, a poorly water-soluble, weakly basic drug.

Amorphous solid dispersions of albendazole:HPMCP:HPMC (2:1:1 w/w) were produced by the solvent evaporation method from an ethanol–dichloromethane solvent system. Using a gastric transfer dissolution method, these authors were able to demonstrate that according to its weakly basic nature, albendazole dissolves extensively in acid, but then rapidly precipitates following the transition into neutral pH. Conversely, the amorphous dispersion with the HPMCP:HPMC carrier showed minimal dissolution in acidic media followed by rapid release in neutral media and prolonged supersaturation. The results of this dissolution study are shown in Fig. 10.16.

The *in vivo* performance of the dual polymer solid dispersion system was then evaluated in two groups of rabbits: (1) rabbits of normal gastric acidity (pH approximately 1) and (2) rabbits with low gastric acidity (pH > 5). Crystalline albendazole physically mixed with lactose was used as a control for this study. The results are provided in Table 10.18. In both groups, the solid dispersion yielded higher exposures versus the control; however, the difference was most pronounced in the group with low gastric acidity where the AUC from the solid dispersion formulation was greater than three times that of the physical mixture. Considering the dissolution results, it was concluded that crystalline albendazole dissolved moderately well under normal gastric conditions, but minimally when gastric acidity was reduced.

Fig. 10.16 Dissolution behavior of albendazole from solid dispersions in media of pH 1.2–6.5; (filled square), physical mixture; (filled circle), solid dispersion with HPMC and HPMCP; (open circle), solid dispersion with HPMC; (open square), solid dispersion with HPMCP. Adapted from Kohri et al. (1999)

On the other hand, the amorphous dispersion formulation was able to generate relatively high levels of dissolved albendazole irrespective of the gastric conditions. Therefore, exposure was much lower for the physical mixture when gastric acidity was reduced, whereas exposure was less affected by the change in gastric conditions for the solid dispersion formulation. Hence, bioavailability enhancement from the amorphous albendazole:HPMCP:HPMC system was a result of the carrier's ability to generate and maintain supersaturated concentrations of albendazole in neutral pH environments. These authors thus demonstrated a delivery system for albendazole that is unaffected by fluctuations in the gastric environment. This represents a significant improvement to therapy with albendazole as the variability inherent to oral delivery was substantially reduced.

This example aptly demonstrates the utility of HPMCP in amorphous solid dispersion systems as a concentration enhancer in neutral pH environments. It also illustrates the corresponding improvement to the oral absorption of poorly water-soluble drugs.

Table 10.18 Pharmacokinetic parameters after administration of albendazole (5 mg/kg) to rabbits in a cross-over study. Adapted from Kohri et al. (1999)

| Parameter | Normal gastric acidity | | Low gastric acidity | |
|---------------------------------|------------------------|------------------|---------------------|------------------|
| | Physical Mixture | Solid Dispersion | Physical Mixture | Solid Dispersion |
| C _{max} (µg/mL) | 2.1±0.2 | 2.4±0.4 | 0.5±0.2 | 1.4±0.2* |
| T _{max} (h) | 40±0.8 | 3.7±0.7 | 6.3±1.6 | 6.7±1.1 |
| AUC _{0-24 h} (µg*h/mL) | 22.4±3.5 | 31.8±4.7* | 6.4±2.6 | 24.8±5.8* |
| t _{1/2} (h) | 2.8±0.4 | 5.8±1.7 | 4.8±1.6 | 4.6±0.8 |
| MRT (h) | 7.7±1.1 | 10.6±2.0* | 12.0±3.2 | 13.3±2.3 |
| Bioavailability (%) | 67.6±17.9 | 94.9±12.9* | 21.3±9.9 | 68.8±13.2* |

This is an early example of perhaps the most widely used ASDD formulation approach for oral delivery of poorly soluble molecules today. Since HPMCP is thermally labile, spray drying is perhaps the best process to apply to the manufacture of amorphous systems containing this polymer as exposure to thermal stress is minimal.

10.8.10.7 Cyclosporine with a Nonpolymer Carrier

In a study conducted by Lee et al. (2001), a spray-dried solid dispersion formulation utilizing a nonpolymeric carrier was developed for cyclosporine A (CsA) and evaluated against the commercial product Sandimmune®, a microemulsion-based soft gelatin capsule formulation. Microspheres of CsA with dextrin and sodium lauryl sulfate (SLS) were produced by spray drying and optimized in terms of drug–excipient ratio by dissolution testing. The optimum CsA/SLS/dextrin ratio with respect to in vitro drug release was found to be 1/3/1 (w/w/w). This formulation was selected for comparative evaluation of in vivo performance against pure CsA powder and Sandimmune in a single dose oral administration study in dogs. The pharmacokinetic data from this study are provided in Table 10.19.

These results revealed that both the spray-dried dispersion and commercial CsA formulations produce substantial improvements in oral absorption over the pure drug powder. Improved absorption from the spray-dried formulation versus Sandimmune was also observed, although the differences were not statistically significant. The similarity in oral absorption produced by the spray-dried formulation versus the commercial formulation represents a significant potential benefit to CsA therapy as the spray-dried formulation is in a preferred solid form and produced by a more straightforward process. Owing to the inherent disadvantages of liquid versus solid formulations and the complicated nature of the soft gelatin encapsulation process, spray drying is a more viable means of improving CsA therapy via formulation. Hence, this study exemplifies the potential opportunities to simplify existing commercial products and their corresponding processes by applying spray-dried solid dispersion technology.

Table 10.19 Pharmacokinetic parameters of CsA after oral administration of CsA products to dogs

| Parameters | C_{\max} ($\mu\text{g}/\text{mL}$) | T_{\max} (h) | AUC ($\mu\text{g}^*\text{h}/\text{mL}$) |
|-------------------------|--|-----------------|---|
| CsA powder alone | 0.46 ± 0.15 | 2.13 ± 0.48 | 2.81 ± 1.16 |

10.8.11 Examples from Industry

Currently, there is only one pharmaceutical product on the market formulated as a spray-dried amorphous dispersion. However, there are several examples of drug molecules formulated by this technology which have reached late stage development. It is important to note that the increase in the number of poorly water-soluble molecules in development pipelines is a relatively recent event, and thus amorphous drug-delivery systems, particularly in commercial use, are also in their infancy. Also, considering the lengthy drug development process and the frequency at which programs are halted, it is not surprising that few spray-dried amorphous formulations have been commercialized. The absence of commercialized products is certainly not an indication of the limited commercial viability of spray drying or amorphous delivery systems. In this section, the commercial and late-stage clinical success of ASDD systems is highlighted by reviewing a few key examples.

10.8.11.1 Etravirine

Etravirine (TMC125) is an HIV-1 specific, non-nucleoside reverse transcriptase inhibitor indicated in combination with other antiviral agents for the treatment of HIV-1 infection. Etravirine was granted accelerated approval by the U.S. Food and Drug Administration in January 2008. The product is marketed by Tibotec Pharmaceuticals under the brand name Intelence[®] and is available in tablets of 100 and 200 mg strengths.

Etravirine is poorly water soluble and exhibits low to moderate permeability and hence is classified as a BCS IV compound (Kakuda et al. 2008). The dose selected based on phase IIb trials was 800 mg twice daily delivered from a tablet formulation produced by conventional granulation (Kakuda et al. 2008). Concurrent to phase II studies, a formulation development program was conducted with the aim of reducing dose and corresponding pill burden (Kakuda et al. 2008). From this program, a spray-dried amorphous solid dispersion formulation was developed, the details of which are provided in patent application WO2007141308 (Kiekens et al. 2007). This patent application describes a spray-drying process in which etravirine is spray dried with HPMC 2910 5 mPa.s from solution in a co-solvent system of

Table 10.20 Pharmacokinetic parameters of etravirine after a single (day 1) administration of phase III formulation at doses of 100 and 200 mg (test) and phase II formulation at a dose of 800 mg (reference)

| Parameter | Phase II Formulation 800 mg twice daily (reference) | Phase III formulation 100 mg twice daily (test) | Phase III formulation 200 mg twice daily (test) |
|---|---|---|---|
| Number of Patients, n | 32 | 33 | 27 |
| Median t_{\max} , h (range) | 4 (2–8) | 4 (2–6) | 4 (3–8) |
| Mean C_{\max} , ng/ml (\pm SD) | 70.6 (\pm 72.7) | 54.9 (\pm 54.0) | 125.9 (\pm 96.0) |
| Mean AUC_{0-12h} , ng*h/ml (\pm SD) | 434 (\pm 437) | 312 (\pm 331) | 745 (\pm 660) |
| LSM | | | |
| C_{\max} (90% CI) | – | 0.81 (0.65–1.00) | 1.97 (1.59–2.45) |
| AUC_{0-12h} (90% CI) | – | 0.72 (0.59–0.88) | 1.91 (1.54–2.36) |

Adapted from Scholler et al. (2005)

dichloromethane and ethanol. Also, described is the inclusion of micro-crystalline cellulose suspended in the feed solution, presumably for the purpose of increasing the bulk density of the powder.

The tablet developed from this solid dispersion formulation was found to yield a ninefold increase in exposure over the phase II formulation in a single-dose pharmacokinetic study in healthy subjects (Scholler et al. 2005). In HIV-1-infected patients, tablets of 100 and 200 mg strength were evaluated against 800 mg of the phase II formulation with twice daily administration (Kakuda et al. 2008). The pharmacokinetic parameters generated from this study are shown in Table 10.20. From these results, it was determined that 200 mg twice daily of the spray-dried tablet formulation produced exposures in the range of the 800 mg twice daily dose with the phase II formulation. This represented a fourfold decrease in dose with corresponding decrease in pill burden. Based on this study, the spray-dried tablet formulation was selected for phase III clinical trials. Eventually, the amorphous spray-dried tablet formulation of etravirine became the final marketed formulation (EMA 2008). This example demonstrates the commercial viability of amorphous spray-dried dispersions and the potential enhancement of therapies with poorly water-soluble drugs with respect to reduction of dose and pill burden.

10.8.11.2 Telaprevir

Telaprevir, also known as VX-950, is a hepatitis C virus protease inhibitor being developed by Vertex Pharmaceuticals in association with Tibotec and Mitsubishi Tanabe Pharma that is currently in phase III clinical evaluation with an anticipated approval date of May 2011. Owing to insolubility of the molecule in water, oral formulations of telaprevir containing a crystalline form of the API do not provide sufficient exposure to achieve therapeutic efficacy. Absolute bioavailability following

Fig. 10.17 Rat PK study with various telaprevir spray-dried amorphous dispersion formulations. Reproduced from Cui et al. (2006)

oral administration of micronized crystalline telaprevir in rats is less than 0.5% (Cui et al. 2006).

In order to improve the solubility characteristics and oral bioavailability of telaprevir, an ASDD formulation strategy was evaluated. United States Patent Application 2006/0089385 describes compositions in which telaprevir is dispersed in an amorphous state in a pharmaceutically acceptable polymer by spray drying. Examination of the application reveals that the preferred compositions contain the amorphous drug in a single-phase system with a cellulosic polymer, i.e., hypromellose or hypromellose acetate succinate, along with a solubility enhancing surfactant, i.e., sodium lauryl sulfate or Vitamin E TPGS. Figure 10.17 shows results of a formulation screening study conducted in rat models which appears to indicate that the HPMC/Vitamin E TPGS formulation yields the greatest exposure. This patent application claims enhanced bioavailability with the amorphous dispersion composition relative to the crystalline drug, and although the extent of this improvement is not known, the progression of the molecule into phase III clinical trials is a good indication that the formulation has enabled therapeutically effective oral delivery of telaprevir.

Additionally, United States Patent Application 2010/0011610 describes FSD of telaprevir solid dispersions. The FSD process produced dry material with significantly greater particle sizes and bulk powder densities over traditional spray drying,

Table 10.21 Pharmacokinetic parameters of various forms of ivacaftor in rats

| Drug form | Dose (mg/kg) | AUC ($\mu\text{g}\cdot\text{h}/\text{mL}$) | T_{max} (h) | % F |
|--|--------------|--|----------------------|------------------|
| 85% Amorphous drug | 50 | 135.5 \pm 27.6 | 6.0 \pm 0.0 | 95.0 \pm 20.0 |
| | 200 | 371.9 \pm 46.1 | 6.0 \pm 0.0 | 61.0 \pm 7.0 |
| Crystalline drug in aqueous vehicle | 50 | 8.0 \pm 1.2 | 4.0 \pm 0.0 | 5.5 \pm 0.8 |
| | 200 | 16.9 \pm 3.0 | 4.7 \pm 1.2 | 3.1 \pm 0.3 |
| Crystalline drug in PEG | 50 | 135.1 \pm 43.0 | 5.5 \pm 1.0 | 74.0 \pm 23.0 |
| | 200 | 431.5 \pm 101.1 | 14.5 \pm 11.0 | 67.0 \pm 16.0 |
| Solid dispersion | 25 | 90.1 \pm 8.1 | 6.0 \pm 0.0 | 111.0 \pm 10.0 |
| | 100 | 260.8 \pm 28.4 | 6.0 \pm 0.0 | 109.0 \pm 12.0 |

Adapted from Hurter et al. (2011)

thus enabling direct compression of the end product (Bittorf et al. 2010). For further discussion of the FSD processes used in this example, see Method Capsule 8.4. With the application of FSD technology to the spray-dried formulation of telaprevir, significant improvement in manufacturing efficiency of the final tablet dosage form is achieved. Thus, in the case of telaprevir, spray-drying technologies improved not only bioavailability but also drug product manufacturing.

10.8.11.3 Ivacaftor

Ivacaftor (VX-770) is an experimental drug candidate being developed by Vertex Pharmaceuticals that is indicated for the treatment of cystic fibrosis and is currently in phase III clinical trials. The molecule exhibits solubility-limited absorption with an oral bioavailability of only 3–6% in rats when administered in a crystalline form (Hurter et al. 2011). A solubility enhanced form of ivacaftor is therefore required to achieve therapeutic efficacy at a reasonable dose.

A series of formulation approaches were evaluated to enhance the bioavailability of ivacaftor, including a spray-dried amorphous dispersion concept. Solubility studies conducted in FaSSIF media revealed that amorphous ivacaftor produced a solubility value of 67.4 $\mu\text{g}/\text{ml}$, which marks a significant solubility improvement over crystalline polymorph form B (1 $\mu\text{g}/\text{ml}$). The ASDD concept utilizing HPMCAS as a carrier was then developed to employ the solubility improvement provided by the amorphous compound in a stable and viable formulation. As shown in Table 10.21, the solubility enhancement provided by the amorphous form of the molecule resulted in a substantial increases in oral bioavailability over the crystalline API in aqueous and PEG vehicles. The ASDD formulation of ivacaftor in HPMCAS generated exposures in excess of 100% relative bioavailability at both 25 and 100 mg/kg doses. This marked a significant improvement in oral absorption over the crystalline compound in both vehicles and a moderate improvement over amorphous drug, particularly at higher doses. This study revealed that the ASDD formulation concept substantially increased exposure of ivacaftor and enabled therapy at lower doses

with a stabilized amorphous form of the drug. The progression of this molecule into phase III demonstrates yet again the value of spray drying with respect to generating viable drug products from poorly water-soluble molecules.

10.8.11.4 Torcetrapib

Torcetrapib is another example of a developing drug molecule whose therapeutic efficacy was enabled by formulation as an amorphous solid dispersion system by spray drying. Torcetrapib is a cholesterylester transfer protein inhibitor which was being developed by Pfizer Inc. before the program was terminated during phase III clinical trials. As described in Example I of WIPO filing WO/2005/011636, a torcetrapib:HPMCAS (1:3 w/w) amorphous solid dispersion formulation was produced by spray drying from solution in acetone (Beyerinck et al. 2005). This “solubility improved” form of torcetrapib was incorporated into an osmotic pump-controlled release tablet and coated with an immediate release layer of atorvastatin, as described in WIPO filing WO/2006/082500 (Berchielli et al. 2006). This combination therapy was found to be effective in lowering cholesterol levels during clinical trials; however, due to increased mortality rates and cardiovascular events, the program was halted late in development.

10.9 Spray Drying for Inhalation

Pulmonary drug delivery has long been employed for the treatment of respiratory diseases. It is generally accepted as the default route of administration for the treatment of asthma and chronic obstructive pulmonary diseases. The lung is very attractive for drug delivery due to its large surface area (up to 100 m²) and low enzymatic activity which provides a controlled environment for systemic absorption of medications (Labiris and Dolovich 2003). This is especially relevant for proteins that are often subjected to rapid enzymatic degradation. Therefore, research in this field has attracted many pharmaceutical companies, and many advances have been made in all areas of development related to this field, i.e., particle engineering, formulation technologies, and delivery devices. Despite the lack of commercial success of Pfizer’s product Exubera[®] (inhalable insulin), its development was a major breakthrough with respect to particle engineering and formulation for inhalation products. This section will be focused on particle/powder characteristics that are important to inhalation and how spray drying can be a useful technology with respect to particle design.

The performance of powders for inhalation is related mainly to (1) aerodynamic particle size and (2) powder dispersibility (Weiler et al. 2010). Product performance can be assessed by *in vitro* determination of fine particle fraction (FPF), for instance, by the use of an Andersen Cascade Impactor. The typical particle size for inhalation products is in the range of 1–5 μm. However, more important than the absolute particle

Fig. 10.18 PulmoSpheres™ solid foam particles. Reproduced from Vehring (2008) with permission from Springer

size is the aerodynamic diameter which takes into account particle density and shape. For further details on particle design for inhalation and the application of spray-dried particles, see Vehring (2008).

Particles produced by spray-drying possess inherently better properties than particles produced by common top-down technologies (micronization processes). They tend to be spherical, having less points of contact between particles when compared to the flat surfaces of micronized particles. Therefore, with spray-dried powders cohesive forces are lower, dispersibility is better, and free particle fractions (FPF) are greater (Weiler et al. 2010). Also, spray-dried powders tend to present densities less than 0.5 g/mL and, in some cases, even lower than 0.1 g/mL which improves the aerodynamic diameter. Given that low density or hollow particles are advantageous for inhalation, several formulation technologies were developed to produce such materials by spray drying. Among those, Pulmosphere® is of particular interest. This technology involves spray drying a fluorocarbon-in-water emulsion stabilized by a long chain phospholipid, e.g., dipalmitoylphosphatidylcholine – pulmonary endogenous surfactant (DPPC) (Tarara et al. 2007; Weers 2000). The sudden removal of the fluorocarbon constituent leaves a hole in the particle surface. In this way, perforated hollow particles are formed as depicted in Figure 10.18. Their density is very low (less than 0.05 g/ml) and their aerodynamic properties are quite amendable to inhalation (Vehring 2008; Weers 2000).

Besides particle size, spray drying also enables the formation of different particle morphologies, namely by tuning the corrugation of the particle surface. By tuning particle corrugation, a smaller radius of curvature in the contact zone between particles can be achieved, thereby reducing cohesion forces and improving powder

dispersibility (Weiler et al. 2008). This optimization may be performed by adjusting some spray-drying process parameters such as drying temperature and feed concentration that have a direct impact on the Peclet number (namely, on the evaporation rate). An increase in both parameters will accelerate the evaporation rate and shell formation which will lead to a more spherical and less corrugated particle.

In order to control particle size, density, and morphology by spray drying, all components must be in solution. This typically forms an amorphous product; thus, the use of stabilizing excipients (e.g., sugars, polymers) is required in many cases. The spray-dried particles of Exubera[®] exemplify such a case. They consisted of insulin and a buffered composition of stabilizers comprising sodium citrate, glycine, and mannitol (Vehring 2008). Therefore, the concepts of spray-dried solid dispersion stabilization are also applicable to spray-dried particles for inhalation. However, the selection of stabilizers must take into account the specificities of lung delivery, namely approval for this mode of administration and safe dosing levels.

The most challenging aspects in the development of a spray-drying process for an inhalable powder are: (1) the generation of very fine particles and (2) process yield. Regarding the former, the use of two-fluid nozzles or even high pressure two-fluid nozzles with very high atomization ratios (in many cases above 10) is usually necessary. In this respect, pressure nozzles are unable to produce the required droplet size distribution, even for very high pressures (200 bar). However, in many cases even using high atomization ratios, the particle-size distribution obtained is too coarse and feed concentration must be tuned. It is not uncommon to use feed concentrations between 1 and 2% w/w in spray-drying processes for inhalable products. Obviously, the throughput will be reduced with such low feed concentrations, but that is an unavoidable compromise.

The collection of these small and low-density particles is also a challenge with traditional cyclone systems as yields lower than 60% are common. For high-value products, namely proteins, this is unacceptable from a commercial perspective. Therefore, optimized cyclone designs, or even the use of filter bags as a collection system, are required.

10.10 Emerging Applications

10.10.1 Spray Congealing

Spray congealing consists of atomizing a molten mixture into fine droplets followed by contact with a cold gas to force rapid solidification. The process is similar to spray drying and, in fact, the equipment required to perform both processes is basically the same. The advantage of the spray-congealing process over spray-drying one is that it is solvent free and provides higher throughputs. The final product also presents clear advantages. The absence of solvent evaporation results in nonporous, smooth spherical particles, as seen in Fig. 10.19. Consequently, the product typically contains large particles (250–2,000 μ) and high densities resulting in free flowing

Fig. 10.19 Spray-congealed particles obtained in a pilot-scale equipment. Reproduced with permission from Hovione FarmaCiencia SA

powders suitable for downstream processing, such as direct compression (Patel and Chen 2001).

Spray congealing consists of preparing a molten mixture comprising the drug and suitable excipients in a vessel by homogenization at temperatures at least 10°C above the melting point or glass transition temperature. The molten material is then fed to a congealing chamber where it is atomized into fine droplets by a suitable atomizer similar to those used in conventional spray drying (e.g., rotary, two-fluid or pressure nozzle). The molten droplets are then solidified on contact with a co-current cold process gas stream. The solid particles are separated from the gas using a cyclone or filter bag in a similar manner to spray drying.

The melt may be prepared by: (1) dissolving the drug in the molten excipients, (2) suspending the drug in the molten excipients, (3) dissolving the excipients in the molten drug, or (4) suspending the excipients in the molten drug. Amorphous solid dispersions are only formed in the case where the drug is in the liquid state, either dissolved in the excipients or melted (cases 1 and 3).

The preparation of the melt is one of the most challenging aspects of the spray-congealing process. The solubility of drugs in polymers is often limited which leads to low drug loads. Moreover, their stability at relatively high temperatures is, in many cases, insufficient. In order to overcome this issue for heat-sensitive products, melting and homogenization of the molten feed may be performed in line and in a continuous manner by using a screw extrusion system (single screw or twin-screw) and feeding directly to the atomization nozzle (Appel et al. 2005). In this way, the drug is subjected to high temperatures for a much shorter duration.

Spray congealing offers a key advantage over a typical hot-melt extrusion process with respect to downstream processing. Specifically, solidification of the melt

and the production of spherical particles with a defined particle-size range that is achieved in a single step unit operation. In this way, secondary processing is avoided like spheronization or milling that are often required following the melt extrusion process.

A challenge of spray congealing is the requirement for atomization of high-viscosity feeds into fine droplets. In order that atomization can be performed, the viscosity of the melt should be below 20,000 cP, preferably less than 10,000 cP. The feeding line and atomizing nozzles should be kept at a temperature equal to or above the melt point to prevent clogging. All atomizing nozzles suitable for spray drying are theoretically suitable for spray congealing; however, due to higher viscosities, rotary nozzles are preferred.

Regarding the particular aspects of the formulation, all excipients that are solid at room temperature and melt without degradation may be used in spray congealing. However, those with relatively moderate glass transition temperatures or melting points are preferred. Excipients used in hot-melt extrusion are also well suited for spray congealing: polymers like Eudragit E100, PEGs; surfactants like Gelucire 44/14, polyethylene glycol fatty acid esters, and poloxamers; solubilizers such as alcohols like benzyl alcohol, sorbitol, mannitol; and esters like ethyl oleate and ethyl caprylate (Patel and Chen 2001). The function of the solubilizers is to increase the drug solubility in the melt, thereby increasing the drug load in the formulation.

10.10.2 Spray Drying for Micro-encapsulation

Micro-encapsulation can be defined as the entrapment of an active ingredient by a protective wall. The wall may be designed to protect the active ingredient from oxidation, light, pH, enzymatic degradation, etc. The wall can also be used for taste masking, to improve powder attributes (e.g. flowability) or to produce controlled release particles (Ré 1998; Shaidi and Han 1993). It has been widely applied in the food and pharmaceutical industries mainly for protective or controlled release formulation applications.

There are several methods to produce micro-encapsulated materials, such as coacervation, molecular inclusion, emulsification, and *in situ* polymerization among others. Spray drying can be used with several of these techniques as a micro-encapsulation method or merely as drying/isolation process. As a continuous and gentle process amenable to heat-sensitive materials, spray drying is particularly useful as a physical method for micro-encapsulation. It is therefore the most common and cost-effective way to produce micro-encapsulated materials in the pharmaceutical and food industries (Gharsallaoui et al. 2007).

In terms of process, micro-encapsulation by spray drying is achieved by suspending or emulsifying the active ingredient in a solution/emulsion containing the dissolved wall materials. This solution may then be homogenized to decrease the suspension/emulsion particle size before feeding to the spray drier. The feed is then atomized in the nozzle and during drying the dissolved materials precipitate to form a

shell around the active ingredient. In this section, wall materials and the spray-drying process parameters that impact micro-encapsulation efficiency will be discussed.

10.10.2.1 Wall Materials

The selection of wall materials depends on the objective of the micro-encapsulation process and the physico-chemical properties of the active ingredient. They play an important role in flowability, mechanical stability, and shelf-life (Ré 1998). They should be highly soluble in the process solvent and have adequate film-forming ability. The most common wall materials used in micro-encapsulation by spray drying are the following:

- Carbohydrates (starches, maltodextrins, and sucrose)
- Gums and gelatins (arabic gum, xanthine, and gelatin)
- Cellulose based polymers (hydroxypropylmethylcellulose acetate succinate, cellulose acetate phthalate, and hydroxypropyl methyl cellulose)
- Polylactic acid (PLA) and polylactide-co-glycolide (PLGA) (biodegradable polymers)
- Acrylate-based polymers (polymethacrylate and polyethylmethacrylate)

These materials are chosen to provide high solubility in the spray-drying solvent, emulsification properties, film-forming ability, good performance during spray-drying process (related to glass transition temperature and stickiness), and low to moderate viscosities at relatively high concentrations (close to 50% w/w).

Carbohydrates

Among the carbohydrates, maltodextrins and modified starches constitute good candidates for micro-encapsulation by spray drying. They are highly soluble in water and yield solutions with low viscosity. They also have good spray-drying properties, namely, high glass transition temperatures, little tendency to stick to equipment walls, and produce relatively dense powders. However, carbohydrates have poor film-forming capacity which is important for encapsulation efficiency and especially in the retention of volatile constituents. This can be solved by adding gums (e.g. gelatins, arabic gum) to the solution. The mass ratio between carbohydrate/gum varies, but it is typically greater than 1 (Bayram et al. 2005). Another benefit of using gum is the improvement of emulsification properties in the formulation which can lead to enhanced bioavailability (Bruschi et al. 2003).

Gums and Gelatins

Spray-drying pure gums may be challenging due to their poor drying behavior associated with low glass transition temperatures. They are typically used together with other wall materials, namely carbohydrates, as discussed previously.

PLGA/PLA

Poly(lactic-co-glycolic acid) is a biodegradable and biocompatible copolymer. It degrades in the body to form lactic and glycolic acid monomers which are by-products of natural metabolic pathways. This biodegradable polymer has been the subject of intense research in drug delivery in recent years (Langer 1990; Putney and Burke 1998). The use of PLGA/PLA and associated micro-encapsulation techniques are well described in the scientific literature (Wischke and Schwendeman 2008).

Examples of marketed PLGA micro-encapsulated drugs produced by spray drying are Bucerelin acetate marketed as Suprecur MP[®] (Japan) from Mochida Pharmaceutical (licensed from Aventis), and Bromocriptine marketed as Parlodel[®] from Sandoz (Wischke and Schwendeman 2008).

10.10.2.2 Particular Features of the Spray-Drying Process for Micro-encapsulation

Micro-encapsulated particle formation depends on the balance between the solvent evaporation rate and the diffusion rate of wall materials in the liquid phase during the drying process. This balance can be quantified by the Peclet number (Vehring 2008). According to their influence on this balance, spray-drying process parameters affect particle size, density, morphology, residual moisture, and micro-encapsulation efficiency.

A study on micro-encapsulation of lycopene (Shu et al. 2006) demonstrated that feed and spray-drying temperatures influenced encapsulation efficiency. The authors found that there was an optimum temperature for the micro-encapsulation process. Increasing the solution temperature was found to improve the atomization process by decreasing the solution viscosity. The use of very high drying temperatures led to the breakage of the particle shell due to the increase in vapor pressure of the entrapped solvent. This ultimately resulted in poor encapsulation efficiency. Therefore, the selection of drying conditions, namely temperatures, is of critical importance not only for process performance (yield) but also for product quality and encapsulation efficiency. In the latter aspect, the visualization of particles by scanning electron microscopy provides a fast and reliable method to assess the effect of the drying process on the integrity of the microparticles.

Another important feature when spray-drying suspension for micro-encapsulation purposes is the ratio between the particle size of the suspended material and the droplet size generated in the atomization process. Obviously, the droplet needs to be larger than the material to be encapsulated. In this particular case, the increase in solution viscosity due to the use of polymers may be beneficial because it enables the generation of larger droplets (Shu et al. 2006).

It is important to note that the presence of suspended solid particles must be taken into account when selecting the atomization nozzle. For obvious reasons, the

dimension of the suspended particles or agglomerates must be smaller than the minimum passage of the nozzle. Given that nozzle blockage may have a catastrophic effects on the spray-drying process, in-line filters are usually employed. Their pore size is designed to be smaller than the orifice, but sufficiently large to allow passage of a great majority of the suspended particles.

Another important aspect is abrasion of the nozzle caused by the expulsion of suspended particles at high velocities. This causes additional erosion of the nozzle and a corresponding decrease in atomization efficiency over time. Therefore, careful selection of nozzle type and material of construction is recommended along with routine verification of nozzle performance. In this particular situation, two-fluid nozzles represent a more robust solution than pressure nozzles and are preferred in cases where the suspended particles are large or very abrasive. The pressure nozzle is also used in some cases for suspensions; however, the material of construction must be sufficiently hard, such as tungsten carbide. The compatibility of the suspension with the associated high-pressure pump must also be assessed.

10.11 Summary

Spray drying is a mature technology that has been used industrially since the mid-nineteenth century and long used in the pharmaceutical industry for API and excipient manufacturing. In this chapter, the process fundamentals, process components, and equipment options have been reviewed to provide the reader with the fundamental understanding necessary to begin practicing this technology. The application of spray-drying technology to the formulation of poorly water-soluble drugs was reviewed with particular focus on ASDD systems. The development process for ASDD formulations was discussed along with considerations for final dosage form production pertinent to the various stages of new drug development. Examples of ASDD systems from the pharmaceutical literature were reviewed along with industrial examples of marketed or close-to-market products. These examples not only provide the reader with practical case studies to consider regarding the use of spray drying for the formulation of poorly water-soluble drugs but also illustrate the commercial viability of the process. Finally, the application of spray-drying technology to inhaled drug delivery was discussed, as well as emerging applications of the process pertinent to poorly soluble compounds, i.e., spray congealing and micro-encapsulation. In conclusion, this chapter has demonstrated the applicability of spray-drying technology to the formulation of poorly water-soluble drugs at all development stages. The recent market and late-stage clinical success of drug products based on spray drying described herein indicate the increasing importance of the technology to the pharmaceutical industry with regard to enhancing therapies with poorly water-soluble drugs.

Method Capsule 1

Preparation and Characterization of Spray-Dried Microparticles

Based on the method reported by De Jaeghere et al. (2000)

Objective

- Produce and characterize amorphous spray-dried microparticles of CGP 70726 with Eudragit L100-55 for enhanced oral absorption

Equipment and Materials

- CGP 70726
- Eudragit L100-55 (methacrylic acid copolymer)
- Methanol
- Büchi Mini Spray Dryer, Model 190
- Malvern Mastersizer® 2000
- PW 1729 X-ray generator

Method

- Feed preparation: In 300 g of methanol, dissolve CGP 70726 (1% w/w) and Eudragit L100-55 (4% w/w) with stirring.
- Spray-drying parameters:
 - Nozzle type: pneumatic two-fluid
 - Nozzle diameter: 0.5 mm
 - Collection system: cyclone
 - Drying gas: nitrogen
 - Feed: methanolic solution, 5% (w/w) solids
 - Feed rate: 4 mL/min
 - Inlet temperature: 50°C
 - Outlet temperature: 37–42°C
 - Aspirator setting: 15
- Morphology assessment: PXRD
- Particle-size analysis: laser light diffraction
- In vivo performance: single dose, oral administration in beagle dogs ($n=4$)

Results

- The average production yield of the spray-dried micro-particles for two runs was 67%
- The spray-dried microparticles were determined to be amorphous by PXRD
- The mean particle diameters of two spray-dried microparticle batches were $10.0 \pm 1.5 \mu\text{m}$ and $9.2 \pm 1.3 \mu\text{m}$ as determined by laser light diffraction.

- The amorphous spray-dried microparticles substantially enhanced the oral absorption of CGP 70726 over the crystalline drug (plasma levels not quantifiable).
- The amorphous spray-dried microparticles produced exposures that were greater than twofold that of nanoparticles produced by an emulsion–diffusion method in the fed state.

Method Capsule 2

Polymer Selection for an ASDD System by Supersaturated In Vitro Dissolution Screening

Based on the method reported by Curatolo et al. (2009).

Objective

- Employ a supersaturated in vitro dissolution test (micro-centrifuge method) to rank order the performance of polymers as carriers for compound 5 in ASDD systems

Equipment and Reagents

- Compound 5 (API), pure crystalline and amorphous
- Polymers: HPMCAS-MF, CAP, CAT, HPMC, HPMCP, PVP
- Phosphate buffered saline, pH 6.5
- Mobile phase: 60/40 1.7% ammonium ascorbate/acetonitrile
- Controlled temperature box at 37°C
- Micro-centrifuge tube (polypropylene, Sorenson Bioscience Inc.)
- Vortex mixer (Fisher Vortex Genie 2)
- Micro-centrifuge, Marathon, Model Micro A
- Pipette (Gilson Pipetman P-100)
- HPLC (Hewlett Packard 1090 HPLC, Phenomenex Ultracarb ODS 20 analytical column, absorbance measured at 215 nm with a diode array spectrophotometer)

Method

- Amorphous solid dispersion formulations of compound 5 (10% w/w) and the various polymer carriers were produced by spray drying from organic solution.
- In a controlled temperature box at 37°C, 4.0 mg of each ASDD powder was weighed into an empty micro-centrifuge tube. Then, 2.0 mL of phosphate buffered saline (pH 6.5) was added to the tube (theoretical maximum drug concentration 200 µg/mL).
- The tube was then closed, timer started, and the tube was mixed continuously for 60 s with a vortex mixer on the highest speed.

- The tube was transferred to the centrifuge and allowed to stand for 6 min; then centrifuged at $13,000\times g$ for 60 s.
- A 25 μL sample was removed from the supernatant using a pipette at 10 min after the timer was started.
- The solids in the centrifuge tube were then re-suspended by vortex mixing for 30 s.
- The centrifuge tube was returned to the centrifuge and allowed to stand undisturbed until the next sample time point.
- At each time point (5, 10, 20, 40, 90 min) the tube was centrifuged, supernatant sampled, and solids re-suspended as described.

Results

- All ASDD formulations showed significant initial supersaturation relative to the pure crystalline and amorphous compound 5. The rank order of C_{max} was as follows: HPMCAS-MF > CAP > CAT > HPMC > HPMCP > PVP > pure API (crystalline and amorphous).
- Subsequent precipitation of supersaturated compound 5 was seen for all ASDD formulations. The rank order of extent of supersaturation for the formulations was as follows: HPMCAS-MF > CAP > CAT > HPMC > HPMC P > PVP.
- From this study, HPMCAS-MF was identified as the optimum polymer carrier in an ASDD system with compound 5 with respect to in vitro dissolution performance.

Method Capsule 3

Spray Drying of AMG-517 with HPMCAS-MF

Based on the method reported by Kennedy et al. (2008).

Objective

- To prepare amorphous solid dispersions of AMG-517 in HPMCAS-MF at 15% and 50% drug loading.

Equipment and Reagents

- AMG-517, micronized free base (API)
- HPMCAS-MF (AQOAT AS-MF, Shin-Etsu Chemical Company)
- Ethyl acetate (99.5% minimum)
- Büchi Mini Spray Dryer, Model B290
- Malvern Mastersizer 2000 equipped with a Hydro 2000 μP wet dispersion cell
- Phillips automated X-ray powder diffractometer, X'Pert PRO

- Modulated DSC, Q1000 by TA Instruments
- 40°C/75% RH stability chamber

Method

- Feed preparation: HPMCAS-MF was dissolved in ethyl acetate at a concentration of 2% (w/w). AMG-517 was then dissolved in the polymer solution to a concentration of 0.353% or 2% (w/w) to produce drug:polymer ratios of 15:85 and 50:50.
- Spray-drying parameters:
 - System: Open cycle
 - Nozzle type: 48 KHZ ultrasonic atomizing nozzle, 2 W power supply
 - Atomizing air: focusing nitrogen at 30 SLPM
 - Collection system: cyclone
 - Drying gas: nitrogen
 - Drying gas flow rate: 300 SLPM
 - Feed: ethyl acetate solution, 2.353% and 4% (w/w) solids
 - Feed rate: 0.75 mL/min
 - Inlet temperature: 75°C
 - Aspirator setting: Bypassed
- Morphology assessment: PXRD
- Determination of T_g 's: Modulated DSC
- Particle-size analysis: laser light diffraction
- Stability assessment: accelerated storage at 40°C/75% RH
- In vivo performance: single dose, oral administration in cynomolgus monkeys ($n=6$)

Results

- Powder yields for the 15% and 50% drug load AMG-517:HPMCAS-MF formulations were 80.5% and 50% respectively.
- Median particle size (volume based diameter d_{50}) was 34.75 and 40.7 μm for the 15% and 50% drug load ASDDs, respectively.
- At both drug loadings, the ASDD formulations were determined by PXRD to be amorphous and found by MDSC to be single-phase systems with T_g 's of 106 and 98°C for the low and high drug load formulations, respectively.
- The ASDD systems were found to remain PXRD amorphous after six months storage at 40°C/75% RH.
- The 15% drug load ASDD formulation in a capsule (with 5% SDS) yielded 163% greater exposure in monkeys as compared to micronized crystalline AMG-517 in aqueous suspension.

Method Capsule 4

Fluidized Spray Drying of VX-950 (Telaprevir) with HPMCAS

Based on the method reported by Bittorf et al. (2010)

Objective

- Employ fluidized spray drying (FSD) to produce an ASDD product composed of VX-950 and HPMCAS suitable for direct compression, i.e., greater average particle size and bulk density versus traditional spray drying.

Equipment and Materials

- VX-950 (telaprevir)
- HPMCAS (Aqoat, Shin-Etsu)
- Dichloromethane
- 8,000 L stirred tank reactor
- Niro PSD-4 spray dryer (Drying capacity 1,250 kg/h) configured in FSD mode (closed cycle)
- Pressure nozzle (Spraying Systems MFP (Maximum Free Passage) SK Series SPRAYDRY® Nozzles Series variety, orifice 52 with core 27)

Method

- Feed preparation: Charge VX-950 (85% w/w) and HPMCAS (15% w/w) to the stirred tank reactor. Then add sufficient dichloromethane to achieve a solids content of 20% (w/w). Stir until a clear solution is obtained while keeping the reactor at 20°C.
- Fluidized Spray-drying parameters:
 - Drying gas: nitrogen, co-current
 - Feed: dichloromethane solution, 20% (w/w) solids
 - Feed rate: 151 kg/h
 - Feed pressure: 22 bar
 - Inlet temperature: 75 ± 3°C
 - Outlet temperature: 35 ± 5°C
 - $\Delta P_{\text{cyclone}}$: 10 – 12 mm H₂O
 - Fines return position: middle
 - Fluid Bed 1 temperature set point: 40°C
 - Fluid Bed 2 temperature set point: 35°C
 - Fluid Bed 3 temperature set point: 30°C

Results

- Product properties:
 - Bulk density: 0.32 g/mL
 - Tap density: 0.41 g/mL

- d10: 16.47 μm
 - d50: 60.03 μm
 - d90: 151.05 μm
 - Span 2.24
 - Distribution: unimodal
- Product obtained was suitable for direct tablet compression.

Method Capsule 5

Spray Congealing of Vitamin E

Objective

- Employ spray congealing to produce amorphous Vitamin E

Equipment and Materials

- Vitamin E
- Büchi Mini Spray Dryer, Model B290 equipped with spray congealing features

Method

- Feed preparation: Charge Vitamin E in a thermo regulated vessel and heat up to 60°C (keep temperature above at least 10°C).
- Spray congealing:
 - Drying gas: nitrogen, co-current
 - Feed: Vitamin E melted
 - System: Open cycle
 - Nozzle type: two-fluid nozzle
 - Collection system: cyclone
 - Drying gas: nitrogen
 - Drying gas flow rate: fan at 100%
 - Inlet temperature: -5°C
- Morphology assessment: SEM
- Particle-size analysis: laser light diffraction

Results

- Powder yields 80%.
- Median particle size (volume based diameter d_{50}) was 40 μm .
- Smooth spherical particles

Method Capsule 6

Micro-encapsulation of Itraconazole

Objective

- Micro-encapsulation of itraconazole by spray drying

Equipment and Materials

- Milled itraconazole ($Dv_{90} < 10\mu$)
- Gelatin
- Sucrose
- Deionized water
- Niro Mobile Minor

Method

- Feed preparation: a solution of Gelatin was prepared in hot water (60°C) at a concentration of 2% w/w. Sucrose was added (Sucrose:Gelatin 4:1). After sucrose dissolution itraconazole (10% of total solids) was added.
- Spray drying:
 - Drying gas: nitrogen, co-current
 - Feed: Suspension of itraconazole
 - System: Closed cycle
 - Nozzle type: two-fluid nozzle
 - Collection system: cyclone
 - Drying gas: nitrogen
 - Drying gas flow rate: 80 kg/h
 - Atomization gas flow rate: 2.6 kg/H
 - Feed flow rate: 1.3 kg/h
 - Inlet temperature: 150°C
 - Outlet temperature: 80°C
- Morphology assessment: SEM
- Particle-size analysis: laser light diffraction

Results

- Powder yield: 85%.
- Median particle size (volume based diameter d_{50}) was 25 μm .
- Particle morphology: corrugated spheres

Chapter 11

Pharmaceutical Cryogenic Technologies

Wei Yang, Donald E. Owens III, and Robert O. Williams III

Abstract Poor bioavailability associated with poorly water-soluble compounds remains a challenging issue in drug development. Particle engineering may be used to improve the physicochemical properties of poorly water-soluble compounds, thereby enhancing the bioavailability. Cryogenic technologies, including spray freeze drying (SFD), spray freezing into liquid (SFL), and thin film freezing (TFF), are “bottom-up” precipitation processes to generate amorphous nanostructured aggregates with significantly enlarged surface area, higher dissolution rates, and supersaturation, via rapidly inducing nucleation followed by particle growth arrest through stabilization via polymers and solidification of the solvent. This chapter provides detailed description of each cryogenic process, formulation guidelines, and characterization analyses. Finally, examples of cryogenically engineered drug compositions with improved in vitro and in vivo macroscopic performance are provided to illustrate the potential benefits of cryogenic technologies, especially TFF.

11.1 Introduction

11.1.1 Therapeutic Shortfalls of Poorly Water-Soluble Drugs

In modern drug discovery processes, routine use of high-throughput screening, combinatorial chemistry, and computer-aided drug design appear to result in a higher prevalence of lead compounds of increased molecular weight and lipophilicity,

despite the high efficiency of the automated processes. About 60% of these drug candidates exhibit poor aqueous and nonaqueous solubility (Gao et al. 2008). Among which, for those with high permeability through biomembranes, classified as Biopharmaceutical Classification System (BCS) Class II drugs, the poor dissolution rate limits drug molecules released into biological fluid contacting the absorbing mucosa (Rasenack and Muller 2002). Basically, it is in the form of an aqueous solution that a drug can be absorbed into the systemic circulation and exert its therapeutic effect. Consequently, the poorly water-soluble drugs often result in low and highly variable bioavailability, and sub-optimal therapeutic effects in patients, particularly when delivered via the oral administration (Muller et al. 2001; Patravale et al. 2004).

11.1.2 Solid Dispersion/Solution, Supersaturation

To improve the bioavailability of poorly water-soluble drugs, defined as the rate and extent of the drug that reaches systemic circulation, new technologies and innovative formulations and drug delivery systems were explored to improve dissolution properties of poorly water-soluble drugs throughout the past decade. These include more conventional techniques such as the use of surfactants, cyclodextrin inclusion complexation, emulsification processes, co-solvency, salt formation, powder milling, and spray drying. However, these attempts have been of limited success, and each was found with inherent problems of their efficacy or stability of the final product.

The increased amount of excipients required to formulate the poorly water-soluble drugs may potentially increase side effects, resulting in low patient compliance. Alternatively, invasive dosage forms such as parenteral formulations have to be developed to address the challenges being presented. However, with even less pharmaceutically acceptable excipient options, solubilization of drug is practically limited (Liu 2000).

Salt formation is one of the commonly used means to increase aqueous solubility of poorly water-soluble drugs. Despite the unionized form being much less soluble than its salt, of further interest, therapeutically, it is the unionized form that more readily penetrates biological membranes to exert therapeutic effects (Martin et al. 1993).

Mechanical milling was generally used to reduce particle size. However, it generates particles with irregular shape and a wide range of size distribution. Moreover, thermo-degradation is another issue associated with milling process. Spray drying is also not an ideal method of choice due to only 50% dry product recovery (Esclusa-Diaz et al. 1996).

To overcome these shortcomings, novel technologies such as hot-melt extrusion, particle engineering by use of supercritical fluid, nanomilling, and solution-based micro-/nanoparticle precipitation (Betageri and Makarla 1995; Mawson et al. 1997; Rogers et al. 2001; Sarkari et al. 2002; Hu et al. 2004b; Matteucci et al. 2007) have

been developed to enhance saturation solubility of poorly water-soluble drugs. It may be practical to increase apparent solubility and/or the dissolution rate via alteration of the solid-state form.

Solid dispersion typically refers to systems in which drug particles are homogeneously distributed throughout a solid matrix of excipient(s). This system provides the possibility of reducing the particle size of drugs to nearly a molecular level in order to transform the drug from the crystalline to partially amorphous morphology. A solid solution results when the drug is molecularly dispersed throughout a solid matrix, i.e., complete amorphous morphology (Kapsi and Ayres 2001), in which the particle size of the drug has been reduced to its absolute minimum without any crystalline drug domains (Leuner and Dressman 2000). The amorphous form of a drug has a higher thermodynamic chemical potential than its crystalline counterpart.

Additionally, exposure area of drug to the dissolution media was also greatly enhanced due to significantly increased surface areas of drug compositions obtained in this way. Therefore, poorly water-soluble drugs in the solid solution/dispersion exhibit higher dissolution rates and higher saturation concentration than their intrinsic solubility of crystalline form of drug, i.e., they can produce supersaturated solutions (Betageri and Makarla 1995). Generation of supersaturation provides higher number of free drug molecules in the solution available for absorption, thereby leading to enhanced bioavailability.

11.1.3 Solubility Advantage of Nanoparticles

Production of drug-loaded nanoparticles for the poorly water-soluble drugs is an alternative and promising approach to overcome their low aqueous solubilities and the consequential low bioavailabilities (Muller et al. 2001). Nanoparticles are currently defined as single particles with a diameter less than 100 nm. Agglomerates of nanoparticles can be larger than 100 nm in diameter but may be de-agglomerated either with weak mechanical forces or by dispersing in a solvent.

Although micronization can increase dissolution rate of the poorly water-soluble drugs by reduction of particle size and thereby increased surface area, it does not increase equilibrium solubility. Often, for drugs with very low aqueous solubility, the achieved increase in dissolution rate is limited and insufficient to provide significant enhancement of bioavailability (Muller et al. 2001). However, when the drug particle sizes were deducted in the 100-nm range, they dissolve more quickly and achieve supersaturation versus the micronized drug particles, as described by the Noyes–Whitney and Ostwald–Freundlich equations (Grant and Brittan 1995). Both particle dissolution kinetics and solubility are size dependent. Thus, the dissolution of drug nanoparticles *in vivo* is usually accompanied by an increase in bioavailability (Hintz and Johnson 1989; Borm et al. 2006).

Furthermore, novel investigation of supersaturation levels of drug nanoparticles in aqueous media demonstrated significantly higher values than the much larger

microparticles of drug composition, which have the potential to crystallize during slow dissolution (Matteucci et al. 2007). Amorphous nanostructured formulations of poorly water-soluble drugs have also been developed to enhance therapeutic effectiveness (Yang et al. 2008a).

11.1.4 Overview of Cryogenic Technologies

Cryogenic particle engineering technologies were developed to improve the solubility and dissolution properties by creating nanostructured amorphous particles with dramatically enlarged surface area at very low temperature conditions, in contrast to micronized crystalline form of poorly water-soluble drugs (Hu et al. 2002; Rogers et al. 2003a; Hu et al. 2004a, b, c; Overhoff et al. 2007a). Cryogenic technologies basically can be categorized into micro-/nanoparticle precipitation technologies or the so-called “bottom-up” particle engineering technologies, with the mechanism of inducing a rapid change in solute solubility to generate solid particles. As well known, solubility is largely determined by the bonding interactions between the solute and solvent on a molecular level; it is also heavily influenced by external factors including temperature, pressure, polarity of the solvent, and pH. Sudden shift of one of these factors can generate strong driving forces to induce nucleation leading to particle formation. Cryogenic technologies utilize cryogens, such as liquid nitrogen, to induce abrupt temperature change of a system containing solubilized poorly water-soluble drug molecules alone or along with excipient molecules. The rapid cooling rates of up to 1.0×10^6 K/s may produce stable amorphous nanostructured particles with significantly enlarged surface areas to facilitate rapid and higher-level dissolution in biological fluids, thereby enhancing bioavailability.

Generally, cryogenic technologies involve the rapid freezing of single solvent or co-solvent-based solution containing drug alone or alone with stabilizer or solubility enhancer. The generated frozen material is then lyophilized to remove the solvent by sublimation like traditional lyophilization and atmospheric freeze drying (ATMFD) (Derle et al. 2010), thus yielding a dry powder of high surface area. Cryogenic processes can be defined by the type of injection device (capillary, rotary, pneumatic, and ultrasonic nozzle), location of nozzle (spraying onto or into a cryogenic liquid, or applying the solution onto a cryogenic substrate), and the composition of cryogenic liquid, such as liquid hydrofluoroalkanes, liquid nitrogen, liquid argon, compressed fluid carbon dioxide, and organic solvents.

In this chapter, spray freeze drying (SFD), spray freezing into liquid (SFL), and thin film freezing (TFF) cryogenic technologies for pharmaceutical applications will be discussed in detail. Examples of recent studies using the cryogenic technologies with step-by-step procedures to engineer poorly water-soluble drugs for improved *in vitro* and *in vivo* performance will be provided and analyzed. It can be readily recognized that applications of these cryogenic technologies may be applied to other freezing processes.

11.1.5 Commonly Used Cryogens

The most commonly used cryogen in cryogenic processes is liquid nitrogen. Liquid nitrogen is a colorless, odorless, and nonflammable liquid that boils at a temperature of approximately -195°C . Due to its natural abundance in the atmosphere, liquid nitrogen is relatively cheap and is readily available in large quantities throughout the world. Compared to other liquid cryogens, it is relatively safe and is already accepted for use in certain medical applications. The primary disadvantages of liquid nitrogen are that it can pose a safety hazard as an asphyxiant and it also exhibits a behavior known as the Leidenfrost effect, which in some instances may actually result in decreased freezing rates for droplets that come into contact with the liquid nitrogen reservoir but are shielded by a vapor layer for some amount of time before direct contact can be made with the liquid nitrogen.

Liquid argon is the most common alternative to liquid nitrogen for use in SFD. It has many of the same advantages as liquid nitrogen and also suffers from some of the same disadvantages such as being an asphyxiating agent. It boils at nearly the same temperature as liquid nitrogen at -185°C ; however, it is typically more expensive than liquid nitrogen and less widely available.

Another group of alternatives are liquid hydrocarbons such as liquid propane, pentane, and hexane. They have relatively higher boiling point and wider availability than liquid argon. However, these systems are considerably more dangerous to work with due to their extreme combustibility. Additionally, these materials have not been accepted or tested in use with pharmaceutical products and could be a potential source of contamination when brought into direct contact with drug products.

11.2 Cryogenic Technologies

11.2.1 Spray Freeze Drying (SFD)

SFD has been used in pharmaceutical research for over 60 years and is likely the oldest of the cryogenic pharmaceutical processing technologies. One of the first published papers in the literature describing this technique was in 1948, which was used as a means to produce protein powders with varying surface areas for subsequent absorption isothermal analysis (Benson and Ellis 1948). SFD has historically been used as a method to process thermally labile compounds such as proteins and peptides as well as even larger biological molecules because, unlike spray drying, no heat is required to obtain the final powder formulation.

In addition to proteins and peptides, SFD was also used for the preparation of amorphous forms of poorly water-soluble drugs, and nonpharmaceutical applications such as food processing (Mumenthalera and Leuenberger 1991; Zijlstra et al. 2007).

11.2.1.1 Process of SFD

SFD is generally described as a three-step process involving the atomization of a drug feed solution or suspension, freezing the atomized droplets, and removal of solvent from the frozen material to obtain a final, typically amorphous, dry powder composition. The equipment and experimental set-up used in SFD are fairly straightforward; however, there are a few choices to consider at each of the three steps of the process.

In the first step of SFD, solutions or suspensions of drug alone or along with excipient(s) are prepared and atomized into small droplets using specialized fluid nozzles or vibrating orifice droplet generators, over a cryogenic vapor to achieve rapid freezing. The primary aspect to consider is the type of nozzle and atomization parameters utilized. To achieve atomization, one of three different types of atomizing nozzles is typically used, including a two-fluid nozzle, an ultrasound or vibration nozzle, and a monodisperse droplet generator. The primary trade-off in these nozzles is particle-size control versus liquid processing rate.

The two-fluid nozzle allows for the highest processing rates up to 15 L/min, but the particle-size distribution created by these nozzles can easily span several orders of magnitude. The particle-size distribution of a given spray created using a two-fluid nozzle is primarily controlled by the properties of the liquid formulation (i.e., the surface tension and viscosity), nozzle geometry, and the flow rate of the liquid and atomizing gas. Two-fluid nozzles are preferred when fast processing is required but droplet-size distribution, hence final particle-size distribution, is not critical. Another disadvantage of the two-fluid nozzle system is that the large volume of atomizing gas utilized by the nozzle can decrease the efficiency and effectiveness of the cryogenic vapor into which the droplets and atomizing gas are being sprayed. This can increase the cost of the overall process and the rate at which cryogen is consumed.

Ultrasonic nozzles allow for relatively high processing rates, potentially up to 100 mL/min, with a better control of particle-size distribution and more importantly do not utilize large volumes of atomizing gas to generate droplets. The particle-size distribution of a spray created using these nozzles is primarily controlled by the properties of the liquid formulation, the properties of nozzle (i.e., orifice size and atomizing surface area), and the frequency of nozzle vibration. Ultrasonic nozzles are preferred for applications where both control of particle size and reasonably high processing rates are needed.

Monodisperse droplet generators are used when extremely precise controls of droplet and particle-size distributions are required. These systems utilize the same technology present in ink jet printing systems to create a controlled monodisperse droplet size; however, the primary disadvantage of these systems is that they have very low processing rates of about 0.1 mL/min. In addition to slow processing rates, these systems are also more prone to clogging and can process only very low viscosity solutions.

The second step in SFD is the freezing of the atomized droplets of drug solution using a cryogenic vapor. In many cases, the cryogenic vapor is created over a

cryogenic liquid reservoir. When the atomized droplets fall through the vapor phase, they then encounter the cryogenic liquid reservoir, which can further ensure that the freezing process is completed. The most commonly used cryogen in SFD is liquid nitrogen vapor. When processing poorly water-soluble drugs using SFD, organic solvents are typically used to prepare the drug in solution/suspension. Very low vapor temperatures are therefore required to ensure the freezing point of the solvents reached.

Once the droplets of drug in solution/suspension have been frozen, the final step is removal of the solvents by sublimation to obtain dry powder form of the engineered drug composition. Traditional lyophilization or ATMFD is typically employed to sublime the frozen solvents. In either case, process conditions during sublimation must be controlled precisely to ensure that no melting occurs, which could potentially undo any advantageous physical properties imparted during the rapid freezing of SFD process.

11.2.1.2 Traditional Lyophilization

Traditional lyophilization is conducted at reduced pressure with vacuum level of few hundred millitorr and low shelf temperature to maintain the frozen SFD-processed material. The lyophilization is broken into two stages known as the primary and secondary drying stages. During primary drying, the temperature and pressure inside the lyophilizer are typically kept below that of the triple point of the solvent. This promotes the sublimation of the frozen solvent from the solid phase directly to the gaseous phase, without allowing any melting. After all or the majority of the bulk solvent has been removed, the process is then shifted to the secondary drying stage, where the shelf temperature is typically brought up to room temperature or higher to remove the molecularly bounded solvent. In most cases, traditional lyophilization is utilized as it is well studied and accepted for pharmaceutical process.

11.2.1.3 Atmospheric Freeze Drying (ATMFD)

ATMFD is conducted at atmospheric pressure conditions and thus does not require a vacuum system. In this case, a cold desiccated gas (typically air or nitrogen) is circulated in and around a mass of frozen product in a fluid-bed-style configuration. For these systems to work properly, the circulation gas needs to be colder than the melting point of the solvent to ensure that no melting occurs. Besides low temperature, the circulation gas needs to have a very low partial pressure of the solvent vapor so that a mass transfer driving force is available to allow for sublimation of the frozen solvent. ATMFD has been utilized and well studied in the food industry (Meryman 1959; Boeh-Ocansey 1983) but only recently, in the past 15–20 years, it has begun to gain some traction in the pharmaceutical literature (Mumenthalera and Leuenberger 1991; Rogers et al. 2003a). Its use in the food industry has been

entirely focused on the removal of water as a solvent and for this process it has shown great promise. In specific cases, especially with freezing processes that result in more porous or discrete ice chips/particles (e.g., SFD, SFL, and TFF), ATMFD has actually been proven to be a much faster and more energy-efficient sublimation process due to the vastly increased heat and mass transfer afforded by the use of a fluid-bed configuration (Mumenthalera and Leuenberger 1991). However, in the case of poorly soluble compounds, the process is complicated by the use of cosolvent systems. As with traditional lyophilization techniques, cosolvent systems using organic solvents with lower melting points may prove to be problematic due to the low processing temperatures required as well as the large volumes of gas separation that may be required. When removing water as a solvent, standard refrigeration techniques can be used on the large scale to dry and recirculate desiccated air to ensure that the partial pressure of water vapor in the air is low, but when the solvent phase is something other than water it may be more difficult to remove these vapors from the recirculated dry gas. Theoretically, it should be possible to utilize ATMFD for the sublimation and drying of drug products created using cosolvent systems, but currently very little research exists on this topic.

11.2.1.4 Pros of SFD Process

One potential advantage of SFD over other cryogenic processes is that it typically results in the highest rate of freezing at around 10^6 K/s when appropriately small droplet sizes are prepared (Engstrom et al. 2007b). This rapid freezing can be useful when working with poorly water-soluble drugs that may have very rapid rates of recrystallization, or when very high surface area powders are needed.

The most common usage of SFD to date has been in the area of the preparation of proteins and peptides for inhalation as a competing and gentler alternative to traditional spray-drying approaches. In contrast to spray drying, SFD process lacks the usage of high and potentially damaging heat to dry powders, and provides very high production yields of more than 95% versus about 50% for spray drying (Maa et al. 1999).

Additionally, the SFD process allows for independent control over both the aerodynamic and geometric particle size of prepared powders, which are critical parameters in the development of formulations for inhalation delivery. This enhanced control is due to the fact that geometric particle size is fixed during droplet formation and subsequent freezing so that a specific final particle size can be selected by controlling the size of droplet that is produced during atomization, whereas with spray drying significant droplet shrinkage and deformation occur due to surface-tension forces imparted as the droplet dries. Aerodynamic diameter, on the other hand, is a function of both geometric particle size and density and, in this case, density can also be controlled independently from geometric size by controlling the solids loading and formulation parameters used to prepare the drug solution that is subsequently processed via SFD (Maa et al. 2004).

11.2.1.5 Cons of SFD process

Compared to other cryogenic techniques such as slow freeze drying in a vial, SFL, and TFF, SFD process can potentially lower biological activity in cases where pure biological compounds without added excipients. SFL and TFF actually result in even higher level of biological activity, because the large droplets used in these processes have relatively less air–water interface. Whereas SFD utilizes atomized fine droplets, a larger air–water interfacial region is created where absorption and denaturation of proteins can occur. However, several recent studies have shown that this effect can be minimized with the incorporation of excipient(s) (stabilizer, complexing agents, cryoprotectants, and surfactants) (Maa et al. 1999; Costantino et al. 2000, 2002; Yu et al. 2006).

11.2.2 *Spray Freezing into Liquid (SFL)*

SFL, one of the novel cryogenic particle engineering technologies, was developed and patented (Williams et al. 2003) and subsequently commercialized by The Dow Chemical Company.

11.2.2.1 Process of SFL

The SFL process involves preparation of a feed liquid, such as an aqueous, organic, or aqueous–organic cosolvent solution, aqueous–organic emulsion, or suspension containing a drug along with pharmaceutical excipient(s) or drug alone: Spray the drug feed liquid under pressure through a small diameter insulating nozzle directly into a liquid cryogen, such as compressed fluid carbon dioxide, helium, propane, ethane, liquid nitrogen, liquid argon, or hydrofluoroethers (Williams, Hu et al. 2003). The rapid cooling leads to immediate freezing of the atomized droplets of feed liquid upon contacting the cryogen. A schematic diagram of SFL process is shown in Fig. 11.1. Then the produced frozen materials were collected and subsequently dried by lyophilization or ATMFd as depicted above, to obtain dry and flowable powders of drug compositions.

The SFL-processed drug powders were generally characterized by micronized structure with amorphous morphology, high surface area, and improved wettability in aqueous media, indicating enhanced dissolution properties of the poorly water-soluble drugs (Hu et al. 2002, 2003; Rogers et al. 2003a, b).

The benefits of SFL process result from intense atomization in conjunction with high freezing rates. Liquid nitrogen has been typically employed as the cryogenic liquid due to nearly instantaneous freezing of the atomized feed liquid resulting from the low boiling point of liquid nitrogen. The nozzle that used to spray feed liquid in SFL process is composed of an insulating material such as poly-ether-ether-ketone (PEEK) tubing to prevent premature freezing of the feed liquid. As the

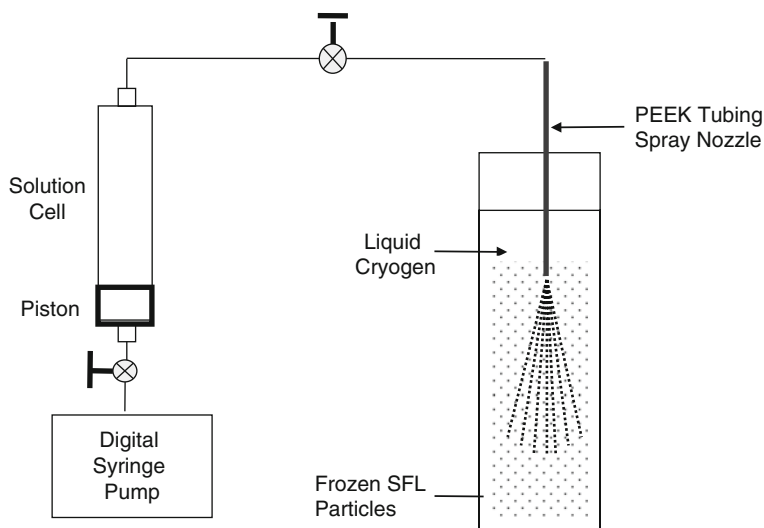

Fig. 11.1 Schematic diagram of spray freezing into liquid (SFL) process. Reproduced from Rogers, Nelsen et al. 2002 with permission from Elsevier

liquid exits the nozzle, liquid–liquid impingement occurs between the pressurized feed liquid exiting the nozzle and the cryogenic liquid, such as liquid nitrogen. The estimated cooling rates are strongly related to droplet particle size of feed liquid, with higher freezing rates observed with smaller droplet sizes due to higher surface area available for heat transfer (Maa and Prestrelski 2000; Engstrom et al. 2007a, b). The cooling rates of SFL process for two different cryogenes, iso-pentane and liquid nitrogen, were calculated to be 8.9×10^6 and 1.1×10^5 K/s, respectively (Engstrom et al. 2007a, b). SFL into iso-pentane produced faster cooling rates despite having a higher temperature (-160°C) compared to liquid nitrogen (-196°C). This was attributed to the boiling of liquid nitrogen around the inserted spray nozzle and/or sprayed feed fluid formed an insulating layer, known as the Leidenfrost effect (Sitte et al. 1987).

11.2.2.2 Pros of SFL Process

The advantages of the SFL process result from intense atomization of drug feed liquid and the high freezing rates. SFL process used liquid nitrogen nearly exclusively as the cryogen. A very high degree of atomization is achieved by spraying directly into the cryogenic liquid as in contrast to spraying into the vapor phase above the cryogenic liquid, because liquid–liquid impingement occurs between the pressurized feed solution exiting the nozzle and the cryogenic liquid (Rogers et al. 2002b). Thus, high freezing rates can be achieved in SFL process due to the low intrinsic temperature of liquid nitrogen and the high surface area of atomized droplets of the drug feed liquid.

Consequently, amorphous morphology of drug compositions can be formed by SFL process, as a result of the ultra-rapid freezing-induced simultaneous vitrification of the feed solution. The high degree of atomization and ultra-rapid freezing (URF) rates led to the formation of amorphous highly porous nanostructured particles (Hu et al. 2002).

Moreover, it is advantageous to use SFL process to make stable submicron protein drug particles. As discussed previously, SFD has the potential to cause protein aggregation due to the large gas–liquid interface in the spraying step. On the other hand, slow cooling by lyophilization (about 1 K/min) can produce stable protein particles; however, the particle size was found to be a minimum of a few microns in diameter with surface areas less than 1 m²/g. The SFL process can minimize exposure to the gas–liquid interface of droplets containing protein, as the spray nozzle was immersed under the surface of the cryogenic liquid. Thus, the SFL process can reduce protein adsorption, denaturation, and aggregation, and, consequently, lead to higher enzymatic activities than that processed by SFD (Yu et al. 2006; Engstrom et al. 2007a, b). Although the cooling rate in SFL is about 10³ K/s, 3 orders of magnitude less than that in SFD, it is sufficiently fast to arrest the growth of submicron protein particles (Engstrom et al. 2009).

11.2.2.3 Cons of SFL Process

Increase in the drug/excipient(s) concentrations of feed liquid normally leads to increases in viscosity of the feed liquid. The relatively high viscosity of the feed liquid can limit the application of SFL, as it can inhibit liquid jet breakup, resulting in slower cooling rates and larger particle sizes and eventually fibers (Barron et al. 2003).

Moreover, removal of solvent from the collected frozen materials by lyophilization is costly for the equipment (lyophilizers) and is a time- and energy-intensive process that could take days or even weeks to finish (Franks 1992).

11.2.3 Thin Film Freezing (TFF)

TFF, also known as cold metal block freezing, initially was used to cool approximately 100- μ m-thick tissue samples at rates between 100 and 10,000 K/s (Gilkey and Staehelin 1986) for nonpharmaceutical application. Impingement and solidification of liquefied droplets onto a cold solid surface have also been used in the electrical and semi-conductor industries to add thin layers of frozen material onto a surface. TFF was also referred as ultra-rapid freezing (URF), spray forming, thermal spray coating, splat cooling, slat quenching solidification, plasma or powder spray deposition, etc. (Overhoff et al. 2009). Recently, TFF has been used as a particle engineering technique to improve the dissolution profiles of poorly water-soluble drugs.

Fig. 11.2 Schematic diagram of thin film freezing (TFF) process. Reproduced from Overhoff, Engstrom et al. 2007 with permission from Elsevier

11.2.3.1 Process of TFF

In a similar manner to the SFD and SFL processes, the first step in TFF process is preparation of a feed liquid containing a drug along with pharmaceutical excipient(s) or drug alone. Then, droplets of the feed liquid that released from a funnel or a pump/dripper system with a controlled flow rate fall from a given height and impact, spread, and freeze on a cooled surface of a cryogenic substrate, as depicted in a schematic diagram in Fig. 11.2. A cryogenic substrate is selected commonly from materials with a thermal conductivity k between 10 and 20 W/(m·K). A rotating cylindrical stainless-steel drum approximately 17 cm in length and 12 cm in diameter with mirror-polished surface was employed to serve as the cryogenic substrate. The drum is hollow with 0.7-cm-thick walls and was filled with cryogen such as dry ice or liquid nitrogen on the inside. As a result of thermal conductivity through the steel, the equilibrium drum surface temperatures were measured to be 223 K or 133 K for dry ice and liquid nitrogen, respectively (Engstrom et al. 2009). The exposure of the cold drum to the atmosphere allowed a thin layer of ice to condense on the drum surface, which may affect the conductivity of the cryogenic substrate, and consequently may affect the freezing rates of the droplets fallen on the drum. To minimize the formation of water-vapor condensation and ice on the steel surface, it is better to place the TFF apparatus in a dry box or humidity-controlled environment with relative humidity less than 15%. Moreover, a blade made by stainless steel or Teflon is mounted along the rotating drum surface to remove the ice immediately before the droplets of feed liquid impacting the drum.

The surface temperature of the drum can be monitored by using a surface moving probe thermocouple attachment. When the temperature on the steel surface reached a proper level, various feed liquids can be applied to the rotating steel drum dropwise from a height of approximately 10 cm. Upon impacting on the cryogenic

Fig. 11.3 Diagram of the thin film freezing process displaying the falling droplet (a), spreading after impact on the stainless-steel surface (b), and during cooling and freezing as a thin film (c) (drawn to scale). Reproduced from Engstrom, Lai et al. 2009 with permission from Springer

surface, the feed liquid droplets (about 2–4 mm in diameter) deformed into thin films (about 100–400 μm in thickness) of disk shape and rapidly cooled until frozen on timescales of 70–1,000 ms, which corresponds to a cooling rate of about 10^2 K/s (Fukai et al. 2000; Pasandideh-Fard et al. 2002), as illustrated in Fig. 11.3 (Engstrom et al. 2009). The frozen disk is scraped off the stainless-steel surface with a blade prior to one full revolution and falls in a collecting pan that filled with dry ice or liquid nitrogen to maintain the frozen disk. After processing a batch, the collecting pan containing the frozen disk is transferred to a lyophilizer where the solvent is removed by sublimation (Overhoff et al. 2007a). The cooling rates in TFF and SFL processes are comparable. Because of rapid conductive heat transfer, resulting in high supersaturation and nucleation rates, TFF process can create powders with high surface area and enhanced dissolution properties, similar to those produced by other rapid freezing technologies. As in other freezing technologies,

the rapid freezing of the feed liquid is critical in preventing phase separation of solute and solvent during freezing, allowing for the compositions to molecularly disperse with each other.

11.2.3.2 Advantages of TFF Process

Although the cooling rate in TFF (10^2 K/s) is lower, compared to those of SFD (10^6 K/s) and SFL (10^3 K/s), it is still sufficient to produce rapid nucleation and to prevent significant particle growth during freezing. In TFF process, the size of the unfrozen channels was sufficiently thin and the increase in the viscosity of the unfrozen solution was sufficiently fast to be able to achieve similar particle sizes and morphologies as for the moderately faster process, SFL, and the much faster process, SFD (Engstrom et al. 2008).

TFF on a cold metal surface bypasses the need to maintain aseptic conditions of a liquid cryogen, for example, liquid nitrogen (Gosselin et al. 2003). The cooling rate of the thin films in TFF may be controlled readily by varying the temperature of the metal surface. Also, the surface temperature of the cryogenic substrate may be measured directly. For SFL and SFD, the complex geometry of the turbulent spray in the liquid nitrogen combined with the Leidenfrost effect can be somewhat difficult to control and monitor (Sitte et al. 1987). In TFF, more concentrated and thus more viscous solutions may be processed, as the droplets are not atomized. However, the thickness profile of the film along the radius of the frozen disk may change with viscosity (Overhoff et al. 2009).

TFF process can provide a high yield of products. In TFF, collection of the frozen thin films of the feed liquid droplets leads to nearly 100% yields, whereas in SFD process yields were about 80% because of the result of entrainment of uncaptured particles in the atomized aqueous stream, particles attaching to the walls of collection vessels, and inefficient separation of the cryogen from the 10–100- μm frozen particles (Johnson 1997; Overhoff et al. 2009).

TFF process offers flexibility of the amount of drugs to be processed. By using TFF, it is feasible to accommodate either small quantities (<1 mL) of drug feed solution due to the high efficiency in collection of frozen films or large-scale production by adding multiple drippers to make droplets in parallel and increasing the length of the drum. The rotating drum of TFF apparatus offers scale-up advantages over other cryogenic particle engineering technologies by becoming more of a continuous freezing process. Thus, TFF process is not limited by the amount of drug to be processed. It is feasible from the early-stage screening of drug in milligram quantity to commercial product manufacturing at a scale of kilograms to tons.

In addition to the advantage of being a simple, efficient, and robust process for freezing, TFF also renders improvement in the stability of the protein product due to the minimized gas–liquid interface of the feed liquid, in comparison to SFD and SFL. It was found that minimizing gas–liquid interface can improve protein stability by limiting the amount of protein that can adsorb to the interface. The surface area

to volume ratio of the gas–liquid interface in TFF was 2 orders of magnitude lower than in SFD, leading to much less protein adsorption and aggregation (Engstrom et al. 2008).

11.2.3.3 Disadvantages of TFF Process

First, maintenance of a low humidity for TFF process increases costs for facility design, equipment, and operation, especially for commercial productions.

Second, with all freezing processes, the quantities and quality of cryogen required for manufacturing production-scale batch sizes could also add to production costs. To date, it is not sure which of the aforementioned cryogenic processes is the most cryogenically efficient (Overhoff et al. 2009).

Additionally, similar to the SFL process, removal of solvent from the collected frozen films by lyophilization is costly, for both equipment (lyophilizers) and energy consumption.

11.2.4 Storage of Dried Powders

If the frozen materials were dried by lyophilization, after the lyophilization cycle was complete, the lyophilizer was filled with dried nitrogen gas upon releasing the vacuum to reduce the exposure of the lyophilized powders to moisture in the ambient air before transfer to packaging area, where the humidity is controlled, commonly to less than 15% RH. The obtained dry powders of the cryogenically processed drug compositions were packaged into hermetically sealed glass containers under dry nitrogen.

11.2.5 Mechanism of Rapid Freezing-Induced Particle Formation

Solubility is heavily influenced by external properties, including temperature, pH, polarity of the solvent, and pressure. Sudden shift of one of these properties can induce nucleation, leading to particle formation. Nanoparticles may be formed by maximizing the supersaturation to induce precipitation instantaneously and then arresting growth (Matteucci et al. 2007). Generally, faster nucleation relative to particle growth leads to a smaller median particle size and more uniform particle-size distribution.

Rapid freezing can be categorized as a precipitation technology, where most of the solvent is separated from the solutes to form ice and the solute phase becomes highly concentrated. Upon initiation of freezing a homogeneous solution, the formation of frozen solvent particles and a drug/polymer-rich phase begin to appear

Fig. 11.4 Frozen morphologies of dilute solution with high supercooling (a), concentrated solution with high supercooling (b), dilute solution with low supercooling (c), and concentrated solution with low supercooling (d). Amorphous ice particles are represented as white domains and solute precipitate as solid dots or gray regions. Reproduced from Engstrom, Simpson et al. 2007 with permission from Elsevier

(Tang and Pikal 2004). The rate of cooling in conjunction with other factors, such as solute concentration, plays a key role in determining the final particle size and structure of the solid powders (Overhoff et al. 2007a). The rate of growth and number of solvent crystals in a freezing solution are determined by the degree of supercooling. Higher supercooling results in more/smaller ice crystals and larger ice-specific surface area (Jiang and Nail 1998). As different freezing methods can produce different supercooling effects, freezing with liquid nitrogen basically can provide the highest supercooling, while solutions subjected to slow cooling rates, for example, freezing with the precooled shelf method, give the lowest supercooling. The solvent in the supercooled solution nucleates and forms crystalline solvent particles which grow during freezing. Increased supercooling, in turn, increases the nucleation rate of frozen solvent particles while minimizing the time for frozen solvent particle growth. When the supercooling is extremely high (rapid freezing rate),

the formation of a vitrified solution may occur in which the nucleation of crystals may be minimized or fully prevented, leading to an amorphous material (Yu 2001; Overhoff et al. 2009).

During freezing, the supersaturation of the solute in the unfrozen domains as a function of the phase diagram establishes a driving force for precipitation to occur. Particle growth under this condition can occur through condensation of individual molecules onto a growing nucleus, coagulation of two growing particles, or Ostwald ripening, which is the growth of larger structures at the expense of smaller structures (van de Witte et al. 1996). Rapid nucleation at high supersaturation all at one time period will produce uniformly sized particles and lower Ostwald ripening (Overhoff et al. 2009).

As depicted in Fig. 11.4, a greater rapid cooling rate will produce a larger number of nuclei and more solid particles separated by thinner ice domains than in the case of slow cooling and slow nucleation. As the cooling domains vitrify, the high viscosity inhibits the further growth of the particles (Engstrom et al. 2007a, b).

11.3 General Guidelines for Cryogenic Technology

11.3.1 *Selection of Solvent/Cosolvent Systems for Cryogenic Processes*

The first step in the cryogenic processes is to make feed liquids. Despite the diversity of feed liquids (solution, suspension, and emulsion) that can be employed for the cryogenic processes, a complete solution of poorly water-soluble drug alone or along with pharmaceutical excipient(s) was mostly reported.

The cryogenic processes produce nanostructured composition of drug within an excipient(s) matrix by rapidly freezing a feed solution using a cryogen and removing the solvent(s) through lyophilization. The primary criteria for selection of proper solvent(s) to make a feed solution containing fully dissolved hydrophobic drug with or without pharmaceutical excipient(s) include sufficient solubility for both drug and excipient(s), proper fluid dynamics for the solvent during spreading and freezing, and easy removal of the solvent(s) by lyophilization.

11.3.1.1 Solubility

Solubility may be defined as the maximum concentration of a substance that may be completely dissolved in a given solvent at a given temperature and pressure. Solute molecules are held together by certain intermolecular forces (dipole–dipole, induced dipole–induced dipole, ion–ion, etc.), as are the molecules of the solvent. In order for dissolution to occur, these cohesive forces of like molecules must be broken and adhesive forces between solute and solvent must be formed. The dissolution process

of solids in liquids involves three steps: (1) the removal of a molecule from the solute; (2) creation of a hole in the solvent; and (3) insertion of the solute molecule into the solvent (i.e., solute–solvent interaction) (Hildebrand and Scott 1950). This interaction between the solute and the solvent is obviously dependent on the physical and chemical nature of the participating molecules. The dissolution of hydrophobic materials, which can dissolve readily in nonpolar organic solvents, differs from that of hydrophilic excipient(s) which tend to dissolve in polar aqueous phase.

Generally, hydrophilic excipient(s) would be incorporated into compositions containing poorly water-soluble drug to improve its wettability. To make a feed solution accommodating both hydrophobic API and hydrophilic excipient molecules in a fully dissolved state, it is critical to choose a proper solvent system. One approach is to mix solvents of different polarities to form a solvent system of optimum polarity to dissolve the solutes of different polarities. This method is referred to as solvent blending or cosolvency. When talking about liquids, the term miscibility rather than solubility may be used to describe the affinity between the liquids (Conventional 2000). Liquids that form a homogenous system when mixed in any proportion are said to be miscible (e.g., water and ethanol). Those in which only certain volume ratios produce homogenous mixtures are said to be miscible in certain proportions (e.g., water and chloroform). Immiscible liquids will not produce a homogenous solution in any proportion (e.g., water and olive oil). For the cosolvent used to make feed solution, the solvents must, obviously, be miscible. For example, tetrahydrofuran/water co-solvent was used to form feed solutions for SFL process, because of the ability to dissolve both a poorly water-soluble drug and hydrophilic excipients (Hu et al. 2002; Rogers et al. 2002b). Some poorly water-soluble drugs have relatively low solubility in the tetrahydrofuran/water co-solvent; later on, acetonitrile, acetone, methanol, methylene chloride, 1,3-dioxolane, tert-butanol, and 1,4-dioxane were used to greatly increase the solubility of drugs. However, the percentage of methylene chloride in cosolvent should be less than 1% to be miscible. Worthy to note is that for the use of low-melting-point solvents, a liquid nitrogen cold trap is necessary to capture the solvent vapor before sucked into vacuum pump during lyophilization.

11.3.1.2 Fluid Dynamics

For SFL process, viscosity of the solvent is an important factor that needs to be considered for preparation of the feed solution to be sprayed through the nozzle into liquid cryogenics. Additionally, the melting point of the solvent(s) used in SFL process is better not higher than 0°C; otherwise, the feed solution may freeze prematurely within the atomizing nozzle before sprayed into cryogenics. Examples of case are tert-butanol and 1,4-dioxane, in which many poorly water-soluble drugs show good solubility. However, due to their relatively high viscosity, 3.62 and 1.54 cP, respectively, compared to other organic solvents, and high melting point for liquid, 25 and 12°C, respectively (see Table 11.1.), they are not proper candidates for SFL. Because the TFF technology applies the droplets directly onto the cryogenic

Table 11.1 The physical properties of the commonly used solvents for cryogenic technologies

| Solvent | Formula | Molecular weight | Boiling point (°C) | Melting point (°C) | Density (g/mL) | Miscibility | Vapor pressure (mmHg) 25°C | Viscosity (mPa·s) 20°C |
|-----------------|--|------------------|--------------------|--------------------|----------------|-------------|----------------------------|------------------------|
| Water | H ₂ O | 18.02 | 100 | 0 | 0.997 | Miscible | 23.78 | 1 |
| Acetone | C ₃ H ₆ O | 58.08 | 56.2 | -94.3 | 0.786 | Miscible | 240 | 0.33 |
| Acetonitrile | C ₂ H ₃ N | 41.05 | 81.6 | -46 | 0.786 | Miscible | 73 | 0.34 |
| t-Butyl alcohol | C ₄ H ₁₀ O | 74.12 | 82.2 | 25.5 | 0.786 | Miscible | 41.25 | 3.62 |
| 1,4-Dioxane | C ₄ H ₈ O ₂ | 88.11 | 101.1 | 11.8 | 1.033 | Miscible | 30 | 1.54 |
| 1,3-Dioxolane | C ₃ H ₆ O ₂ | 74.08 | 75.6 | -95 | 1.06 | Miscible | 70 | 0.66 |
| Ethyl acetate | C ₄ H ₈ O ₂ | 88.11 | 77 | -83.6 | 0.895 | 8.7 | 14 | 0.51 |
| Methanol | CH ₃ O | 32.04 | 64.6 | -98 | 0.791 | Miscible | 13.4 | 1.04 |
| Tetrahydrofuran | C ₄ H ₈ O | 72.11 | 66 | -108.4 | 0.886 | 30 | 170 | 0.55 |

substrate, premature freezing is not a concern and solvents with high melting point may be used.

Nevertheless, TFF process also requires consideration of the fluid dynamics for the solvent during spreading and freezing. The ability of an impinging droplet on the cryogenic substrate to spread into a thin large-diameter disk prior to freezing influences the cooling rate of the thin disk. Danazol/polyvinylpyrrolidone (PVP) powders were produced under the same TFF process except for using acetonitrile and tert-butanol, respectively, as the solvent. It was observed that the powder from acetonitrile solution exhibited more uniform nanostructured surface morphology compared to the powder from tert-butanol solution. The morphological difference was attributed to the cooling rate of the two solvents (Overhoff et al. 2007a; Overhoff et al. 2009). Moreover, solvents of the feed solution with greater thermal diffusivities are more desirable for rapid heat transfer. The rapid heat transfer in TFF process is the result of intimate contact between the solution and cryogenic substrate.

11.3.1.3 Ease of Lyophilization

Freeze drying, i.e., lyophilization, is the commonly used means to obtain dry powder from the cryogenically generated materials by removing the solvent(s). The ideal solvent for freeze drying has the following properties: a high vapor pressure, a melting point either below or slightly above room temperature, a high viscosity, and a low toxicity. It must provide a stable environment for freeze drying and be rapidly and completely removed to produce dry material (Ni et al. 2001).

A variety of different types of organic solvents were used in cryogenic processes, as mentioned in Table 11.1. Most of these water-miscible organic solvents have freezing points below -75°C . The frozen disk made by the low-melting-point solvents tends to melt during lyophilization and it makes a very challenging task for the lyophilizer condenser to catch the sublimed vapor of these solvents. A cold trap between lyophilizer sample chamber and vacuum pump is necessitated to prevent the solvent vapor from being sucked into the vacuum pump.

Accordingly, organic solvents with higher melting point are of great interest for selecting proper solvent for cryogenic process. Acetonitrile, having a melting point of -45°C , viscosity of 0.34 cP, good heat transfer, and the unique ability to dissolve both a hydrophobic drug and hydrophilic excipient(s), was widely employed for many compositions containing poorly water-soluble drug in both SFL and TFF processes to increase drug loading with reduced risk of liquid–liquid phase separation. More importantly, the high vapor pressure of 73 mmHg at 25°C eases the removal of the solvent by lyophilization.

Subsequently, high-melting-point solvents 1,4-dioxane and tert-butanol were often employed in studies of TFF process, which has less concern of premature freezing compared to SFL. Tert-butanol was often used in combination with low-melting-point solvent system for its easy-to-freeze and good lyophilization characteristics. As a result of its high vapor pressure (Table 11.1.) and its crystal morphology, the sublimation rate of tert-butanol is greater than 2.5 times that of water. 1,4-dioxane/water

co-solvent was extensively used to make feed solutions for TFF process (Overhoff et al. 2007a, b; DiNunzio et al. 2008; Yang et al. 2008a, b), mainly due to its relatively high freezing point and vapor pressure which make the freezing and lyophilization processes easily manageable. These solvents prove beneficial by reducing the lyophilization time (Ni et al. 2001) or eliminating the solvent-removal process altogether as some of these solvents sublime at ambient conditions or higher (Tesconi et al. 1999). Moreover, they have low biological toxicity and basically no harmful impact to the environment.

According to these criteria, a solvent with these ideal properties may not exist for cryogenic processes.

Formation of co-solvent systems can mitigate limitations of certain solvents (solubility) while maintaining some of the ideal fluid dynamics and lyophilization characteristics. Combinations of 1,3-dioxolane (solubility enhancer) and tert-butanol (ideal freezing and lyophilization properties), tetrahydrofuran and water (both are solubility enhancers), acetonitrile (solubility enhancer and freezing and lyophilization properties) and water, and 1,4-dioxane (solubility enhancer and freezing and lyophilization properties) and water have been used to generate nanostructured poorly water-soluble drug compositions using cryogenic technologies.

11.3.2 Selection of Excipients, Concentrations for Drug Formulations Using Cryogenic Processes

The ultimate goal of cryogenic particle engineering technologies is to improve the dissolution properties of poorly water-soluble drug by making an amorphous nanoparticulate form of the drug. However, a primary concern of the formed amorphous material is the inherent instability, due to the higher energy state. Amorphous material may automatically convert back to a low-energy crystalline state. Recrystallization of the amorphous drug may be avoided by inclusion of stabilizing hydrophilic excipients in the composition. Principally, stabilizing excipients combat recrystallization of amorphous drug particles by steric hindrance and/or the formation of hydrogen bonds with drug molecules (Khougaz and Clas 2000; Vasanthavada et al. 2005). These stabilizing excipients must be hydrophilic for improving the wetting properties of drug particles; however, the hydrophilic excipients should not be hygroscopic. Otherwise, they absorb moisture easily when exposed to ambient environment, which can lead to morphological instability of the excipient-stabilized amorphous drug particles by either displacing drug molecules from hydrogen-bonding sites or plasticizing polymeric stabilizers (Forster et al. 2001; Vasanthavada et al. 2004).

As morphological instability and poor wettability are the substantial limitations to particle engineering of poorly water-soluble drugs, concessions need to be made in selecting appropriate stabilizing excipient(s), with respect to rigidity for steric hindrance or hydrophilicity. Many readily soluble and/or wettable excipients do not provide adequate steric hindrance of recrystallization due to low melting points or

glass transition temperature (T_g). On the contrary, excipients with high melting points or T_g 's typically have relatively poor wetting properties. Therefore, polymers with high glass transition temperature (T_g) and hydrophilicity, such as PVP and hydroxypropylmethylcellulose (HPMC), are popular candidates to formulate poorly water-soluble drugs for improved aqueous dissolution. To expand the choices of polymers, combinations of rigid and malleable excipients such as surfactants (e.g., poloxamer, sodium dodecyl sulfate, and Tween 80) often can be used to achieve reasonable stability and wettability. Other commonly used polymers include polyvinyl pyrrolidone-covinyl acetate (PVP/VA), hydroxypropylmethylcellulose acetate succinate (HPMCAS), high-molecular-weight polyethylene glycol (PEG), polyvinyl alcohol (PVA), polylactic acids (PLA) and polylactic-co-glycolic acid (PLGA), etc.

Besides polymers, nonpolymeric natural products (e.g., lecithin) and small-molecule hydrophilic excipients (e.g., sugars) can also be employed to enhance wettability and solubility of poorly water-soluble drugs, with better safety profiles. Sugars such as lactose, sucrose, trehalose, and, recently, fructose oligomer inulin were frequently used as an excipient to stabilize amorphous drugs, peptides, and proteins during drying and subsequent storage (Davies and Feddah 2003; Van Drooge et al. 2004). The addition of sugars has been shown to extend the shelf life of amorphous systems by preventing crystallization (Eriksson et al. 2003).

Worthy to note is that excipient to drug ratio is also an important consideration in formulation design. First, excipient to drug ratio may affect the morphology of the engineered drug composition. The T_g of the overall drug composition is a function of the fraction of each component. If there is more amorphous material present in the drug composition, more stabilizing polymer would be needed to be present; otherwise, it may lead to a greater risk of recrystallization. Second, excipient to drug ratio affects hydrophilicity of the engineered drug compositions. It has been demonstrated that as the potency of a poorly water-soluble drug composition increased, the wettability is often decreased, particularly for the matrix system of a drug composition where drug and excipient molecules distribute randomly. Hydrophilic excipients act at the surface of drug composition particles to reduce the solid-liquid interfacial tension between the hydrophobic drug and aqueous media (Sinswat et al. 2005). As potency is increased, a greater proportion of the particle surface area is occupied by drug molecules; hence, the surface is rendered more hydrophobic, i.e., less wettable. Thus, it is often difficult to achieve high-potency drug particles with acceptable wetting properties. However, by carefully selecting excipient(s) and controlling the proportions of drug and excipient(s) in the cryogenically processed drug compositions, it was also possible to achieve high-potency drug compositions with improved wettable surface and high stability against recrystallization. An SFL-processed danazol/PVP K-15 composition with high potency of 91% was reportedly maintained in its amorphous structure and rapid dissolution characteristics after 1 month of cycled stability conditions (-5 – 40°C every 3 h) (Hu et al. 2004a, b, c).

In addition to the considerations for characteristics and stability of drug composition, formulation design also needs to comply with regulatory requirements for

Fig. 11.5 Scanning electron micrographs of TFF-processed powders containing ITZ and hydroxypropylmethyl cellulose phthalate (HP-55) at various solid loading and drug polymer ratios: (a) 4:1HP55 (2%), (b) 1:4HP55 (2%), (c) 4:1HP55 (0.2%), (d) 1:4HP55 (0.2%). Reproduced from Overhoff, Moreno et al. 2007 with permission from Elsevier

final dosage forms. It is important to judiciously select excipients that have been accepted/approved by FDA for specific administration routes. Especially for parenteral and pulmonary deliveries, only very limited excipients are approved for use, mainly including biocompatible and biodegradable materials.

Moreover, the total solid loading (drug plus excipients), particularly the excipient to drug ratio in the feed solution for cryogenic processes, affects morphology and surface area of the cryogenically engineered drug compositions. Typically, a higher solid loading infers denser engineered drug composition powder, accordingly, the lower the surface areas of the powder. Itraconazole and hydroxypropylmethyl cellulose phthalate (HP-55) at 2.0% solid loading demonstrated a porous matrix structure as seen from Fig. 11.5a and b, while decreasing the solid loading to 0.2% formed discrete nanoparticles, as shown in Fig. 11.5c and d. At 0.2% solid loading, low polymer loading showed amorphous string-like structures (Fig. 11.5c), whereas increasing the polymer ratio resulted in more spherical nanoparticles (Fig. 11.5d), indicating that the surface morphologies are strongly influenced by the percentage of polymer in the composition. By manipulating the

solid loading and polymer portion in the feed solution for cryogenic processes, drug compositions with desired characteristics may be tailored. For example, low-density powders of drug compositions intended for pulmonary delivery can be produced from a feed solution with drug loading commonly in the range of 0.5–1% (w/v). To make drug composition powders to be further processed into tablets or capsule dosage forms, the feed solution may be made to above 5% (w/v) if solubility permitted, so that much denser powders can be obtained to press into tablets or fill into capsules.

11.3.3 Properties of Pharmaceutical Powders Made by Cryogenic Processes

Based on the extensive studies of the cryogenic particle engineering technologies, drug compositions processed by these technologies have been shown to create nanostructured amorphous particles with dramatically enlarged surface area and improved dissolution properties, in contrast to crystalline bulk drug. Additionally, these processes allow molecular incorporation of hydrophilic pharmaceutical excipient(s) to drug compositions, leading to improvement of the wetting characteristics of the bulk poorly water-soluble drug powder (Hu et al. 2002; Rogers et al. 2003a, b; Hu et al. 2004a, b; Overhoff et al. 2007a; Purvis et al. 2007; Yang et al. 2008b). The cryogenic technologies are primarily precipitation, i.e., “bottom-up,” processes, allowing for a reduction in the particle size of drug particles without degradation that induced by heating or mechanical process. As discussed in Sect. 12.2.5 amorphous morphology and uniform small particle size result from the very rapid freezing rates of these processes. Both the spray of drug feed solutions to produce tiny droplets and impinging of the feed solution drop on a solid substrate to form a spreaded very thin layer of liquid enable dramatic enlargement of surface area, which, in turn, enhance the rapid freezing process. According to the Noise–Whitney equation

$$dM / dt = AD(C_s - C) / h,$$

where dM/dt is the rate of dissolution, A is the surface area available for dissolution, D is the diffusion coefficient of the compound, C_s is the solubility of the compound in the dissolution medium, C is the concentration of drug in the medium at time t , and h is the thickness of the diffusion boundary layer. With dramatically increased surface area and decreased particle size, the dissolution rate can be increased. Furthermore, the formation of metastable amorphous form yields higher energy states for the drug and thus a greater thermodynamic driving force for dissolution. Therefore, both dissolution rate and the extent of dissolution are improved, i.e., achieved supersaturation of the drug.

The very rapid freezing of the cryogenic processes enables production of amorphous nanostructured pharmaceutical powders with relatively small amounts of

excipient(s) to achieve high drug loadings of commonly 50–86% drug/total solids, while maintaining high dissolution rates.

In addition, cryogenically engineered pharmaceutical powders with the properties described above also offer the versatility of being further assembled into diverse dosage forms for application, such as pulmonary, oral, and parenteral delivery. The most extensively explored application is pulmonary delivery, including application of the engineered pharmaceutical powders directly in powder form to various dry powder inhaler (DPI) devices, making aqueous dispersion of the pharmaceutical powder for nebulizers, and dispersing the pharmaceutical powders in propellants such as hydrofluoroalkanes (HFA) for pressurized metered dose inhalers (pMDI).

Pulmonary drug delivery is of great interest due to its targeted delivery of drug to the pathological sites. However, for inhalation delivery, particle-size distribution and morphology of the drug-containing particles have pronounced effects on drug deposition in the respiratory tract and therapeutic effects. Unpublished data from our laboratory showed that TFF-engineered dry powders containing tacrolimus and nonpolymer excipient (e.g., sugars) featured with low-density (0.01–0.03 g/mL), high-surface-area amorphous brittle matrices composed of sub-500-nm primary structures. The aerodynamic profiles of the tacrolimus dry powders indicated that they are suitable for deep lung delivery by filling the powders into size-3 capsules and used in Handihaler[®] and Easyhaler[®] DPI devices. Similarly, beclomethasone dipropionate dry powders that were engineered by TFF process demonstrated proper aerodynamic profiles for inhalation when applied to Handihaler[®] device, suggesting that TFF-generated low-density, nanostructured micron-sized pharmaceutical powders are suitable for application in DPI.

In recent years, pulmonary drug delivery targeted to the alveoli for systemic absorption has become an increasingly attractive route of administration for poorly water-soluble drugs (Courrier et al. 2002). The concept of improving bioavailability of poorly water-soluble drugs by pulmonary delivery of nanostructured aggregates was reported in a murine model. An amorphous nanostructured composition containing itraconazole:mannitol:lecithin (1:0.5:0.2, w/w/w) made by TFF process illustrated dramatically enhanced supersaturation dissolution profile and aerodynamic properties suitable for deep lung delivery *in vitro*. Inhalation of the nebulized colloidal dispersion of this composition by mice for 20 min produced significantly high drug deposition in lung and effective therapeutic concentration in blood. The observed dramatic improvement in bioavailability of the TFF-processed itraconazole was mainly attributed to the amorphous nature, smaller nanoscaled particle size, and the presence of lecithin, which is biocompatible to lung and acts as a permeation enhancer to facilitate ITZ to permeate through the lung epithelium (Yang et al. 2008b).

Another promising application of cryogenically engineered pharmaceutical powders is their incorporation into pMDIs. Suspension stability in pMDIs is a significant challenge because surfactants that have been approved by FDA for inhalation are insoluble in propellants of pMDI. Commercial pMDI products are therefore perplexed by poor suspension stability with settling observed within minutes. Consequently, it requires patients to shake the pMDI device right before inhalation.

A novel rod-shaped nanoparticle (nanorods) of bovine serum albumin that was used as a model protein drug, created by TFF process, was found capable of forming stable suspensions in HFA against settling for 1 year and produced optimal aerodynamic properties (Engstrom et al. 2009). The excellent suspension stability of the protein particles in HFA was attributed to their anisotropic geometry. Spherical particles pack together in a more efficient manner than anisotropic particles, such as rods [86]. Therefore, open flocs composed of nanorods take up a larger volume and have lower density, compared to flocs containing spherical particles. TFF process is applicable to a wide variety of drugs to make nanorods for pMDI without the need of stabilizing the primary particles.

Besides the excellent performance of the cryogenically engineered pharmaceutical powders in pulmonary delivery, rapid-release tablet formulation containing SFL-processed danazol micronized compositions by direct compression was also reported (Hu et al. 2004a, b, c). The high surface area, high porosity, and amorphous structure of the SFL-processed danazol compositions contribute to their significantly enhanced dissolution profiles. However, these properties may be changed during the process of incorporation of other tablet excipients and tableting compression. By selection of suitable excipients and direct compression without involving water in the tableting, it was found that over 90% of danazol released in only 10 min from tablets containing SFL-processed danazol composition (danazol/PVP K-15/SLS=4:1:1), similar to the dissolution profiles of the SFL composition itself. The amorphous morphology was also maintained. Utilizing high T_g excipient in the SFL-processed composition was contributed to prevent recrystallization of the SFL-processed danazol during the tableting process.

An alternative means is to fill the cryogenically engineered pharmaceutical powders into capsules for oral delivery. A solid solution of itraconazole (ITZ) and enteric polymer cellulose acetate phthalate (CAP) (ITZ:CAP=1:2, w/w) was created by TFF process (DiNunzio, Miller et al. 2008). In vitro supersaturated dissolution results demonstrated significantly lower levels of supersaturation in acidic media and greater extents of supersaturation in neutral media compared to Sporanox pellets, the marketed product of itraconazole. Both the ITZ:CAP=1:2 and Sporanox pellets were filled into size-9 capsules and dosed to rats. The pharmacokinetics study indicated that ITZ:CAP=1:2 achieved 2 times higher oral bioavailability and more rapid onset of action versus Sporanox[®] pellets. The amorphous nature of TFF-engineered ITZ:CAP=1:2, the intestinal targeting, and the increased durations of supersaturation rendered by enteric polymers were needed to contribute to the improved bioavailability.

A novel way recently patented is utilization of hot-melt extrusion process to prepare extrudates employing relatively low-melting/softening-temperature polymer or a blend of polymers as carrier and cryogenically engineered pharmaceutical powders (Miller et al. 2008). It is critical to conduct the extrusion at a temperature approximating or above the softening or melting temperature of the carrier polymer and below the point of solubilization of drug-containing particles in the carrier system, and below the recrystallization point of amorphous drug in the drug-containing particles. Therefore, high T_g excipient(s) need to be employed in the preparation

of cryogenically engineered pharmaceutical powders. The obtained extrudate containing the cryogenically engineered pharmaceutical powder particles can be milled for further tableting or capsule filling for oral administration.

Compared to the conventional dosage forms, the lower amount of excipients and drug in cryogenically processed drug compositions to be delivered to patients can provide increased patient compliance, safety, and therapeutic efficacy of the poorly water-soluble drugs (Yang et al. 2008b).

11.3.4 Analytical Methods Used to Characterize Pharmaceutical Powders Made by Cryogenic Processes

11.3.4.1 Solid-State Characterization

The solid state of the drug and excipient are important aspects of the physical and chemical stability, as well as pharmaceutical and therapeutic performance of the drug product.

Amorphous state, a disordered phase, having similar mechanical and physical properties of a supercooled liquid existing at temperatures below its thermodynamic crystallization temperature but has not been given sufficient time to anneal and crystallize to its thermodynamically stable ordered phase, inherently has a higher degree of molecular mobility (Hancock et al. 1995). Even a small amount of crystalline form of the drug can significantly affect the in-vivo performance of the amorphous drug (Hancock and Parks 2000). Therefore, it is important to monitor and characterize the extent of crystallinity or disorder during formulation development, manufacturing, and over the intended shelf life of pharmaceutical product to ensure a robust and safe formulation by understanding the behavior of these amorphous systems.

Various analytical techniques have been reported for quantifying amorphous or crystalline phase in solids. The classical methods of evaluating the solid state are powder X-ray diffractometry (Newman and Byrn 2003; Shah et al. 2006) and thermal analyses (Clas et al. 1999).

Powder X-Ray Diffractometry (PXRD)

Diffraction techniques are perhaps the most definitive method of detecting and quantifying molecular order in any system. Conventional, wide-angle and small-angle diffraction techniques have all been used to study order in systems of pharmaceutical relevance (Salekigerhardt et al. 1994). Diffraction is defined as a scattering phenomenon in which the incident X-rays, depending upon the phase difference, are reinforced to form diffracted beams (Suryanarayan 1995).

PXRD is one of the most widely used quantification techniques because of its simplicity and it measures differences in periodicities of atoms/molecules in a powder sample (Stephenson et al. 2001). It provides important insight, based on the

degree of long-range order present, into the extent and nature of the crystallinity and microstructure. PXRD patterns of crystalline forms show strong diffraction peaks, whereas amorphous states exhibit diffuse and halo diffraction patterns.

X-ray procedures for the estimation of degree of crystallinity are based upon the measurement of X-ray scattering from the entire sample including the crystalline and amorphous region of the sample. The experimentally measured crystalline and amorphous intensities are proportional to the crystalline and amorphous fraction of the sample. Quantification of amorphous material by PXRD can be achieved by three methods: (1) measuring the characteristic crystalline peak intensities, (2) measuring the integrated peak areas of the principal crystalline peaks, and (3) measuring the intensity of characteristic region of amorphous scattering; of physical mixtures of known crystallinity to yield a calibration curve which is used for further quantification studies (Shah et al. 2006).

Limit of detection (LOD) of crystallinity in amorphous drug compositions of X-ray diffraction is 5–10%, and the limit of quantitation (LOQ) is 2–5% (Nagapudi and Jona 2008). The specificity and accurate quantitative nature of this nondestructive technique make it the first line choice for studying crystallinity of pharmaceutical materials.

Thermal Analysis

Analyses based on thermal energy principle have been widely employed to characterize amorphous pharmaceutical systems.

Crystallization from the amorphous state can be induced by the thermo-analytical techniques to produce an exothermic change whose magnitude is then quantitatively related to the extent of crystallization occurring. This can then be used to determine the crystallinity of a partially amorphous sample provided total crystallization of this sample is known to occur (Salekigerhardt et al. 1994). Differential scanning calorimetry (DSC) in both conventional and modulated modes has been used to quantify the extent of crystallinity.

Amorphous materials can be characterized by their glass transition temperature (T_g). By DSC, T_g is characterized by a change in heat capacity, which is seen as a change in the baseline. The T_g may be important in determining the relative chemical and physical stability of formulations containing amorphous drugs (Yoshioka et al. 1994).

From a pharmaceutical perspective, it was thought that below the T_g the molecular mobility was very low, and long-term product stability can be achieved by storing amorphous pharmaceuticals at sub- T_g temperatures. In the amorphous form of a hypoglycemic agent for diabetes mellitus, with a glass transition temperature of 71°C, no recrystallization was found after a 4-month storage at room temperature in the absence of moisture. However, crystallization occurred after storage at 50°C for 2 months. The extent of recrystallization increased with increasing storage temperature. Some amorphous drugs with high T_g can remain stable for extended times. For example, an API with a T_g of 125°C does not crystallize from the solid state

in the absence of moisture (Clas et al. 1999). By using scanning calorimetry and thermo-mechanical methods, it was found that in order for the average relaxation time constants to significantly exceed the projected shelf life for a pharmaceutical product (approximately 3 years), it was generally necessary to store the amorphous materials as much as 50°C below the glass transition region (Hancock et al. 1995; Hancock 2002).

The LOD and LOQ of crystallinity often tend to be better using DSC, with levels of 1–5% and less than 1%, respectively (Nagapudi and Jona 2008). DSC also requires much less material than PXRD.

Spectroscopy

Spectroscopic methods such as Raman, infrared (IR), and near-infrared (NIR) have also been reported for crystallinity quantitation (Head and Rydzak 2003; Brown et al. 2007). They provide chemically resolved information with small amount of material requirements. However, data interpretation from spectroscopic methods can run into problems because of their inability to unambiguously separate peaks from different phases in the sample.

Solid-state nuclear magnetic resonance (ssNMR) is another powerful technique which as yet has not been widely applied (Lefort et al. 2004). The primary advantage of ssNMR lies in its selectivity and ability to probe a variety of nuclei. Among the above-mentioned methods, ssNMR is the only technique that does not require a pure reference standard for phase quantitation. LOQ down to 0.25% can be achieved when ^1H , ^{31}P , or ^{19}F nuclei are used for quantitation, while LOQ of about 3% can be achieved when using ^{13}C . In spite of the high sensitivity, the usage of ssNMR has been limited due to instrument availability and relatively large amount of material is required (60–200 mg) (Nagapudi and Jona 2008). In contrast, XRPD and DSC have been widely used, as these techniques are usually available in most pharmaceutical labs.

11.3.4.2 Surface Analyses

Scanning Electron Microscopy (SEM)

SEM is recognized as unique tool in the visual examination of solid-state drug compositions and their surfaces. The resolution is of the order of nanometers (magnifications in the range 20–100,000 ×). A fine beam of electrons of medium energy (5–50 keV) scans a gold–palladium-coated sample producing secondary electrons, backscattered electrons, light or cathodoluminescence, and X-rays. The latter allow for X-ray microanalysis for specific elements. SEM is routinely used for imaging particles in the micron and smaller size range and for examining the surfaces of larger particles. The resolution allows identification of specific surface geometric features that are indicative of structural phenomena.

Atomic Force Microscopy (AFM)

AFM, a powerful surface and nanoimaging analytical technique, offers a unique opportunity to examine surface structure of a variety of materials with mesoscopic-scale resolution (10^{-6} – 10^{-9} m) and quantify the individual particle and excipient interaction by direct force measurement in a variety of environmental conditions (Jalili and Laxminarayana 2004). Especially for inhalation drug delivery, AFM is very useful to provide tailored investigations of particle–particle interactions within DPIs, particle–DPI wall interactions, and also perform *in vivo* simulations of inhaled particle–pulmonary surfactant interactions (Sindel and Zimmermann 2001).

AFM can also be used for phase imaging. Surface amorphous domains of sorbitol were reported to be identified and mapped by using both AFM and Raman microscopy (Ward et al. 2005).

Specific Surface Area Measurement

The surface area of a solid material is the total surface of the sample that is in contact with the external environment. It is expressed as square meters per gram of dry sample. Poorly water-soluble drugs are often rendered more available for absorption by reducing the particle size, i.e., increasing the surface area. Surface area is strongly related to the particle sizes, pore size, and the pore volume. The smaller the particle size and pore size, the higher the surface. The larger is the pore volume, the larger is the surface. The surface area results from the contribution of the internal surface of the pores plus the external surface of the pharmaceutical powders. The pharmaceutical powders generated by cryogenic technologies are generally fluffy and porous from visual and microscopic observations. For such porous systems, the contribution of the external surface to the total is very limited.

Physical and chemical gas adsorption and mercury intrusion porosimetry are the most widely used techniques to characterize powders and solid materials. Gas adsorption porosimetry typically can be performed using the Brunauer–Emmett–Teller (BET) theory (Brunauer et al. 1938) which allows for multilayer adsorption. With nitrogen gas adsorption, depending on the equipment used, pore diameter in the range of 0.3–300 nm, i.e., mesopores and macropores, can be determined.

Mercury intrusion porosimetry is another commonly used method to measure surface area of pharmaceutical powders. The principle, based on the Washburn model, consists of registering the volume of pores penetrated at each intrusion pressure, which can be easily transformed into pore size via the Washburn equation (Washburn 1921) to give a complete pore-size distribution (Carli and Motta 1984).

Both of these techniques can provide reliable information about pore-size/volume distribution, particle-size distribution, and specific surface area for porous solids regardless of their nature and shape.

Fig. 11.6 Contact angles formed by a liquid at the liquid, gas, and solid three-phase intersections. Contact angle can be assessed directly by measuring the angle formed between the solid plane and the tangent to the drop surface using optical tensiometry (goniometry)

Contact Angle

Contact angle is a quantitative measure of the wetting of a solid by a liquid. It is defined geometrically as the angle formed by a liquid at the three-phase boundary where a liquid, gas, and solid intersect. Pharmaceutically, wetting is not an end in itself but is the preliminary step in another process, e.g., dispersion or dissolution, both in vitro and in vivo. The improvement in wettability of a hydrophilic character probably was responsible for the increased dissolution rate of hydrophobic drugs (Lerk et al. 1976). Contact angle is therefore often determined as a measure of the surface energetics of drug substances.

Optical tensiometry (goniometry) is a commonly used method to measure contact angles of drug substances, which are compressed to form smooth and flat-faced tablets. Analysis of the shape of a sessile drop of test liquid placed on the flat-faced tablets is the basis for optical tensiometry. Contact angle can be assessed directly by measuring the angle formed between the solid and the tangent to the drop surface, as shown in Fig. 11.6.

11.3.4.3 Other Techniques

Particle Size

Particle size is one of the physicochemical properties influencing the performance of drug product and its manufacturing processability and quality attributes (<http://www.ich.org/>). The influence includes dissolution rate, drug release profiles, and bioavailability; in vivo particle distribution and deposition, absorption rate, and clearance time; aerosolization behavior and performance of respiratory formulations; content and dose uniformity; and flow and packing properties, mixing and segregation of powders, etc.

There are various principles and techniques used for particle-size measurement. Among the techniques most commonly used in the pharmaceutical research and development, microscopy is often applied as an absolute particle-sizing method because it is the only method where the individual particles can be observed, measured, and their shape determined. Static and dynamic light scattering, Coulter

counter (electrical zone sensing), time of flight (TOF), and cascade impactors are also widely used methods (Shekunov et al. 2007).

Pharmaceutical powders generated by cryogenic technologies were found suitable for pulmonary delivery (Vaughn et al. 2006; Yang et al. 2008b). The recent trend of systemic pulmonary drug delivery makes it very important to understand the correlation between the aerodynamic diameter, determined by *in vitro* measurements or *in vivo* lung deposition studies, and different geometric diameters measured by a variety of nonaerodynamic techniques. Andersen cascade impactor (ACI), next-generation impactor (NGI), and time-of-flight aerodynamic particle sizer (APS) are commonly employed to measure aerodynamic particle sizes.

Dissolution

It is well recognized that the low dissolution rate of poorly water-soluble drugs in biological fluids is the rate-limiting step to absorption. Amorphization of poorly water-soluble drugs can increase dissolution rates and achieve supersaturation, thereby the bioavailability (Yamashita et al. 2003). The amorphous forms, due to higher molecular mobility as compared to the corresponding crystalline form, may have enhanced dissolution rate and this difference can then be used to estimate the degree of amorphous content in a given sample. Although the amorphous form will have a higher dissolution rate because of higher free energy, and higher surface area after certain particle engineering processes, there is an inherent risk of recrystallization in the dissolution fluid. Nevertheless, the amount dissolved from a drug composition versus that from the pure crystalline drug, *i.e.*, extent of supersaturation, has been used to quantify crystallinity in drug solid dispersion/solution systems.

Density Measurement

Solid density is a fundamental physical property of pharmaceutical powders. Generally, crystalline state of materials has a higher density than their amorphous counterparts because the atoms in the crystal lattice are located at a minimum possible distance from each other. An increase in lattice disorder (*i.e.*, increase in amorphous phase) usually results in an increase in volume and therefore a decrease in density (Suryanarayan 1985). Hence, density can also be used as an alternative parameter for investigating the crystallinity of pharmaceutical powders. The cryogenic technologies discussed in this chapter can produce amorphous, low-density pharmaceutical powders. Bulk, tapped and true density measurements, as defined by US Pharmacopeia, are commonly used to characterize these pharmaceutical powders.

Dynamic Vapor Sorption (DVS)

DVS provides accurate gravimetric data in conjunction with a control of humidity and temperature. It does this by varying the vapor concentration surrounding

the sample and measuring the change in mass which this produces in a humidity-controlled microbalance system. Gas and vapor absorption occur into the disordered regions located at the surface, and absorption phenomenon is known to accelerate where disordered surface regions are present. Water vapor is most commonly used, though it is possible to use a wide range of organic solvents. Water vapor sorption is particularly a useful method to assess the presence of amorphous material either as a single component or in combination (Costantino et al. 1998; Stubberud and Forbes 1998).

Inverse Gas Chromatography (IGC)

IGC is a vapor sorption technique for studying solids using gas chromatography principles, in which the powder is packed into or coated onto a chromatography column and a series of known nonpolar and polar probe gases are eluted. Interactions between the gas molecules and the stationary phase (powder) result in a characteristic net retention volume, which is used in the determination of free energy of adsorption, powder crystallinity, and other thermodynamic surface parameters (Hickey et al. 2007a).

IGC is nondestructive and considers only the outermost layer of the sample (Feeley et al. 1998), i.e., the region of the substance directly involved during interactions. It is a sensitive technique and recently has found its use in pharmaceuticals, such as in characterization of DPI (Sethuraman and Hickey 2002) and pMDI (Traini et al. 2005) formulations, for which adhesional properties are considered crucial for their aerodynamic performance. IGC can be used for the determination of surface energy and surface acid/base properties which directly influence adhesional properties.

11.4 Examples of Poorly Water-Soluble Drug Compositions made by the Cryogenic Processes with Improved Dissolution Properties

In view of the above description of cryogenic technologies, step-by-step examples of using cryogenic technologies to engineer poorly water-soluble drug compositions to improve their dissolution profiles are provided below.

The majority of published research articles in the field of SFD focus on the preparation of water-soluble biological or proteinaceous materials for inhalation delivery, because of the processing constraints inherent in SFD. It is typically much easier to work with aqueous systems in SFD due to their low viscosity and low freezing point. Here, we provide two examples of poorly water-soluble drugs: cyclosporine A (CsA) and influenza vaccine processed using SFD.

Example 1

CsA, a potent immunosuppressant, is a BCS Class II drug with aqueous solubility of 3.69 $\mu\text{g/mL}$ at 37°C and log P value of 3.0. Previous research studies have shown that the administration of CsA to the lungs in addition to base therapy can increase the overall survival rate of lung transplant patients (Iacono et al. 1997; Costantino et al. 2004). However, due to its poor solubility, previous studies have utilized nebulized CsA in propylene glycol solution for inhalation to increase its bioavailability (Burkart et al. 2003). The inhalation of propylene glycol resulted in the removal of a number of patients from the study due to extreme irritation of the airways despite the use of local anesthesia. The use of rapidly dissolving, amorphous dry powder of CsA would alleviate the issues associated with the use of propylene glycol while still allowing for improved dissolution and bioavailability. Additionally, the higher deposition efficiency obtained by using a DPI would also allow for lower metered doses and lead to improved patient compliance. SFD-processed amorphous dry powders of CsA and inulin were prepared to examine its viability as a pulmonary delivery formulation.

Method Capsule 1 Preparation of a Cyclosporine A solid Dispersion for Inhalation by SFD

Based on the method reported by Zijlstra et al. (2007)

Objective

- To obtain a dry powder formulation of CsA for pulmonary delivery with enhanced chemical and physical properties, such as wetting, dissolution rate, and aerodynamic performance.

Equipment and Reagents

- Liquid nitrogen
- CsA, inulin and *tert*-butyl alcohol
- SFD apparatus equipped with a heater two-fluid nozzle (0.5 mm orifice)
- Christ model Alpha 2–4 stage lyophilizer

Method

- CsA and inulin were first dissolved into *tert*-butyl alcohol and water, respectively, and then mixed at a 40/60 volume ratio with a constant 5% (w/v) solid loading.
- Formulations with CsA to inulin ratios of 10, 20, 30, 50, and 100% were prepared.
- After mixing, solutions were sprayed into liquid nitrogen vapor at a flow rate of 6 mL/min with an atomizing airflow of 500 L/h.

- After spraying, frozen droplets were then collected and placed into a precooled (-35°C) stage lyophilizer.
- Primary lyophilization was conducted with a stage temperature of -35°C and a vacuum pressure of 165 mTorr for 24 h.
- Secondary lyophilization was conducted with a stage temperature of -20°C and a vacuum pressure of 37.5 mTorr for 24 h to obtain the final dry powder formulation.

Results

- After SFD processing, both pure CsA and CsA/inulin formulations showed high specific surface areas ranging from 145 to 185 m^2/g for CsA/inulin formulations and 40 m^2/g for pure CsA.
- Analysis of the secondary structure of the SFD-processed CsA formulations using FTIR confirmed the amorphous nature of these formulations.
- Cascade impaction studies revealed that SFD-processed CsA formulations had high respirable ($>75\%$) and fine particle fractions (50%), making them ideal candidates for inhalation delivery.
- Dissolution testing showed that SFD-processed CsA formulations had superior wetting and dissolution performance compared to physical mixtures of bulk CsA and inulin.

This study highlighted the use of SFD as a method to prepare an amorphous dry powder formulation of CsA and inulin for pulmonary delivery. By utilizing SFD a high surface, wettable, and rapid dissolving formulation was prepared that had superior aerosol performance and enhanced dissolution. Based on these results, SFD process is a viable alternative to prepare CsA formulations for pulmonary delivery in lung transplant patients, compared to the propylene glycol-based CsA formulation.

Example 2

Influenza affects millions of people each year and has a high mortality for the elderly, infants, and other high-risk populations such as immunocompromised patients (Simonsen et al. 1998). Currently, the influenza vaccine products available on the market are all in liquid form and delivered either as a nasal mist or as an intramuscular injection. To ensure the stability of these liquid-based products prior to administration to the patient, cold chain storage and tracking are required, which add cost and limitations on the shipping and handling of these products. The administration of these vaccines via intramuscular injection is also a major hindrance to patient compliance and acceptance, and even the newer nasal administration forms of these vaccines, which are more acceptable to most patients, also still present a significant barrier to acceptance for a smaller subset of the population. This study utilized the SFD process to prepare a dry powder influenza vaccine to examine its viability as a needle-free epidermal delivery formulation.

Method Capsule 2

Preparation of an Influenza Vaccine Powder for Epidermal Delivery by SFD

Based on the method reported by Maa et al. (2004)

Objective

- To prepare a stable and viable dry powder formulation of influenza vaccine for epidermal delivery with high density and narrow particle-size distribution.

Equipment and Reagents

- Liquid nitrogen
- Trehalose, mannitol, and dextran
- SFD apparatus equipped with an ultrasonic atomizer nozzle (60 kHz frequency)
- FTS systems DuraStop lyophilizer

Method

- Influenza vaccines were first concentrated using tangential flow filtration followed by centrifugal filtration until a desired permeate concentration was collected.
- Various formulations were then prepared at a final solid loading of 20% to as high as 35% by the direct addition of trehalose, mannitol, and dextran to the permeate solutions.
- All final solutions were prepared at or below a viscosity of 2 poise to allow for effective atomization.
- Solutions were then sprayed into liquid nitrogen vapor and frozen droplets were then collected and placed into a precooled (-10°C) stage lyophilizer.
- Primary lyophilization was conducted with a stage temperature of -10°C and a vacuum pressure of 100 mTorr for 10 h.
- Secondary lyophilization was conducted at 15°C for 5 h and 25°C for 5 h, both at 100 mTorr, to obtain the final dry powder.

Results

- After SFD processing, all formulations exhibited a D(50) within the range of 30–60 μm , which is preferred for epidermal skin delivery.
- Several formulations also exhibited a tapped powder density of greater than 0.5 g/ml, which is required for effective skin penetration in epidermal delivery.
- Extensive stability and potency testing using sodium dodecyl sulfate–polyacrylamide gel electrophoresis, single radial immunodiffusion assay, and *in vivo* immunogenicity testing in a mouse model all confirmed that the various formulations remained stable and potent after SFD processing with one formulation exhibiting stability for more than 6 months at 25°C .

This study highlighted the use of SFD as a method to prepare a dry powder form of the influenza vaccine for epidermal delivery. By utilizing SFD, a stable dry powder with appropriate particle size and density was prepared with excellent long-term stability and no significant loss of antigen potency. Based on these

results, it would appear that dry powder forms of influenza vaccine prepared by SFD for epidermal delivery is a viable alternative to the current liquid formulations for intramuscular injection or as a nasal mist.

Early studies of SFL focused on developing drug/excipient(s) combinations to achieve dissolution enhancement, increase drug loading capabilities, and on the effect of solvent systems in achieving higher drug/stabilizer ratios while maintaining enhanced dissolution rates.

Example 3

Carbamazepine was the first poorly water-soluble drug used as a model for SFL process. Carbamazepine is an anticonvulsant and mood-stabilizing drug used primarily in the treatment of epilepsy. Although the drug has been in use for more than 20 years, oral administration of carbamazepine encounters multiple challenges, including low aqueous solubility (17.7 $\mu\text{g/mL}$ at 25°C, log P value of 2.45) with high dosage required for therapeutic effect (more than 100 mg/day), a narrow therapeutic window, and dissolution-limited bioavailability (Bertilsson and Tomson 1986). Carbamazepine is classified as a BCS Class II drug (Amidon et al. 1995). The low rate of dissolution in aqueous biological media is considered to be a likely cause of the irregular and delayed absorption issues encountered with the oral delivery of carbamazepine (Moneghini et al. 2001). In vivo pharmacokinetic studies revealed a strong correlation between oral bioavailability and the physical form and formulation of carbamazepine (Hickey et al. 2007a, b), suggesting that improvement of the dissolution properties of carbamazepine can result in improved pharmacokinetics and bioavailability. Rogers and co-workers (Rogers et al. 2002a, b) developed a novel composition of carbamazepine made by SFL process to improve the dissolution profile.

Method Capsule 3

Preparation of Engineered Carbamazepine Compositions by SFL

Based on the method reported by Rogers et al. 2002a, b

Objective

- To enhance the dissolution rate of poorly water-soluble drug carbamazepine by using a novel SFL process to engineer the drug composition.

Equipment and Materials

- SFL apparatus
- Liquid nitrogen
- Carbamazepine, sodium lauryl sulfate (SLS), tetrahydrofuran (THF), and purified water
- Bench-top tray lyophilizer
- Desiccator and desiccant

Method

- Prepare carbamazepine feed solution by dissolving the drug in THF, dissolving the hydrophilic excipient SLS in purified water, as listed in the table below, then mix the organic and aqueous solutions to form a one-phase cosolvent solution with a solid loading of 0.44% (w/v).

| | Component | Solvent |
|---------------|-----------------------|------------------------|
| Organic phase | Carbamazepine, 0.20 g | THF, 29.80 g |
| Aqueous phase | SLS, 0.20 g | Purified water, 59.6 g |

- Fill a clean large 4-liter insulated beaker with liquid nitrogen.
- Spray and atomize the carbamazepine feed solution beneath liquid nitrogen surface at 5,000 psi constant pressure through a 10-cm-long, 63.5- μ m ID PEEK nozzle into the beaker by a syringe pump.
- Monitor liquid nitrogen level in the beaker to ensure that the PEEK nozzle is kept beneath liquid nitrogen level during the spray.
- Collect the frozen material on a 150-mesh sieve or wait till the liquid nitrogen evaporated after the spray is completed.
- Transfer the collected frozen material to a precooled shelf in a tray lyophilizer to maintain the frozen material and remove solvents.
- Store the obtained flowable dry powder of carbamazepine composition at room temperature under vacuum in the desiccator.

Results

- SEM images demonstrated that porous micron-sized particles consisting of carbamazepine and SLS matrix system were created by SFL process.
- XRD indicated that the highly crystalline carbamazepine bulk powder was transferred to complete amorphous state by the SFL process.
- SFL-processed carbamazepine composition was wetted and dissolved immediately in purified water; almost 100% carbamazepine was released within 10 min, significantly greater than carbamazepine bulk powder and the physical mixture of carbamazepine and SLS.

This study was a proof of concept that SFL process can significantly improve the dissolution properties of poorly water-soluble drug.

Example 4

Danazol is a synthetic steroid derived from ethisterone that has low aqueous solubility (0.5 μ g/mL at 37°C) with high permeability across biological membranes (log P value of 4.53) (Bakatselou et al. 1991; Badawya et al. 1996). Therefore, danazol is classified as BCS Class II drug. The oral bioavailability of danazol is dissolution rate-limited. Many techniques have been utilized to enhance the dissolution of danazol. However, because of the practically insoluble nature of crystalline danazol, the improvement of aqueous solubility was limited.

The several different danazol formulations engineered by SFL process were reported (Hu et al. 2002; Rogers et al. 2002a, 2002b). After initial proof-of-concept studies, formulations with high potency and enhanced stability of amorphous state (i.e., achieved high T_g), besides high dissolution rates, were designed.

Method Capsule 4

Preparation of Engineered High-Potency Danazol Compositions by SFL

Based on the study reported by Hu et al. (2004a, b, c)

Objective

- To investigate the use of organic solvents in the SFL particle engineering process to make rapid-dissolving high-potency danazol powders and to examine their particle size, surface area, and dissolution rate.

Equipment and Materials

- SFL apparatus
- Liquid nitrogen
- Danazol micronized powder, polyvinylpyrrolidone (PVP) K-15, sodium lauryl sulfate (SLS), acetonitrile, dichloromethane (DCM), and purified water
- Bench-top tray lyophilizer
- Desiccator and desiccant

Method

- Prepare danazol feed solutions by dissolving the drug and PVP K-15 in various weight ratios in acetonitrile or acetonitrile/dichloromethane mixtures to form solutions with total solid loading up to 1.6% (w/v), as listed in the table below.

| Danzol/PVP K-15 ratio (w/w) | Danzol (g) | PVP K-15 (g) | Acetonitrile (mL) | DCM (mL) | Potency (%) | Solid loading (%) |
|--------------------------------|------------|-----------------|----------------------|-------------|----------------|-------------------------|
| 1:2 | 0.2 | 0.4 | 70 | – | 33 | 0.86 |
| 1:1 | 0.2 | 0.2 | 70 | – | 50 | 0.57 |
| 2:1 | 0.4 | 0.2 | 70 | – | 66 | 0.86 |
| 3:1 | 0.6 | 0.2 | 65 | 5 | 75 | 1.14 |
| 10:1 | 1 | 0.1 | 55 | 15 | 91 | 1.57 |

- Fill a clean insulated container with liquid nitrogen.
- Spray and atomize the danazol feed solutions beneath liquid nitrogen surface, with a constant pressure of 2,000 psi to provide a flow rate of 50 mL/min for the feed solution to spray through PEEK tubing of 127 μ m ID into liquid nitrogen using a syringe pump.
- Monitor liquid nitrogen level in the beaker to ensure that the PEEK nozzle is kept beneath liquid nitrogen level during the spray.

- Collect the frozen material on a 150-mesh sieve or wait till the liquid nitrogen evaporated after the spray is completed.
- Transfer the collected frozen material to a precooled shelf in a tray lyophilizer to maintain the frozen material and remove solvents. A cold trap is connected to the lyophilizer for the compositions prepared with DCM.
- Store the obtained dried powders in glass vials at room temperature under vacuum in the desiccator.

Results

- XRD indicated that the SFL-processed micronized danazol/PVP K-15 compositions with potencies of 50–91% were all amorphous.
- Surface areas of these SFL-processed danazol/PVP K-15 powders were in the range of 28–115 m²/g, in a reversed order to the increasing solid loading of the SFL feed solutions.
- Contact angles of these SFL-processed danazol/PVP K-15 powders were in the range of 22–35 degrees, much reduced compared to 57 degrees of the unprocessed bulk danazol; among the SFL-processed compositions, contact angles increased with increasing potencies of danazol in the compositions.
- SFL-processed danazol compositions exhibited significantly enhanced dissolution rates with 95% of danazol dissolved in only 2 min for the high-potency composition, whereas the micronized bulk danazol dissolved slowly with only 30% of the danazol released in the same time frame.

The rapid freezing of SFL process produced porous, nanostructured aggregates of the danazol/PVP K-15 compositions as seen in Fig. 11.7b, with smooth primary particle size of about 100 nm in diameter as shown in Fig. 11.7c, d, in contrast to the micron-sized crystalline bulk danazol in Fig. 11.7a. Because SFL-processed powders have high surface areas and contain amorphous danazol, enhanced dissolution of the poorly water-soluble drug in aqueous media was achieved.

A subsequent stability study was conducted for the SFL-processed danazol/PVP K-15 powder (75% potency) at cycle conditions (–5 to 40°C every 3 h). It was found that the amorphous structure and rapid dissolution characteristics were maintained after one month of cycled stability conditions (Hu et al. 2004a, b,c). The high stability of amorphous SFL powders was partially attributed to the selection of PVP K-15 as stabilizer in the composition. PVP K-15 has a T_g of 146°C; the interaction of danazol with PVP K-15 may lead to a reduction in the molecular mobility of danazol in the formed solid solution/dispersion of danazol/PVP K-15 powder.

Example 5

Because of the innate hydrophobicity of the poorly water-soluble drugs, there was an upper limit for the drug concentrations that could be dissolved in solvent/cosolvent system. Low drug concentrations in the feed solution for SFL process

Fig. 11.7 Representative SEM images of SFL-processed danazol/PVP K-15 compositions: Bulk micronized danazol (a); SFL danazol/PVP K-15 (50% potency) powder at magnification of 20 K (b); at magnification of 60 K (c); at magnification of 200 K (d). Adapted from Hu, Johnston et al. 2004 with permission from Elsevier

resulted. To further increase drug loading in feed solution, o/w emulsions with higher danazol and excipient concentrations were formulated for SFL process (Rogers et al. 2003b), as the total concentration of drug in the o/w emulsions could be much larger than in the cosolvent because of the high solubility of hydrophobic drug in the internal organic phase of the emulsion.

Method Capsule 5

Preparation of amorphous high-potency danazol compositions using SFL processed o/w emulsions

Based on the study reported by Rogers et al. (2003a, b)

Objective

- To further increase drug loading in feed solution, o/w emulsions with higher danazol and excipient concentrations were formulated for SFL process.

Equipment and Materials

- SFL apparatus
- Liquid nitrogen
- Danazol micronized powder, poly(vinyl alcohol (PVA, MW 22 000), Poloxamer 407, PVP K-15, THF, ethyl acetate dichloromethane (DCM), and purified water
- Rotor-and-stator homogenizer, high-pressure homogenizer
- Bench-top tray lyophilizer
- Desiccator and desiccant

Method

- Prepare danazol SFL solution by dissolving the drug and excipients in THF and water, respectively, then mix the organic and aqueous phases to form feed solution with a potency of 40%, as listed in the table below.

| Formulations | Component | wt. ratio | Solvent | Potency |
|--------------|-----------------|-----------|---------------------------------------|---------|
| Solution | Danazol | 2 | THF/water | 40% |
| | PVA (MW 22 000) | 1 | | |
| | Poloxamer 407 | 1 | | |
| | PVP K-15 | 1 | | |
| Emulsion | Danazol | 20 | Ethyl acetate/ water, or DCM/water | 87% |
| | PVA (MW 22 000) | 1 | | |
| | Poloxamer 407 | 1 | | |
| | PVP K-15 | 1 | | |

- Prepare oil-in-water (o/w) emulsions of danazol for SFL process by high-pressure homogenization. Dissolve danazol and excipients in organic solvents and water, respectively. Slowly pour the organic phase into the aqueous phase under constant mixing, then blend for 1 min using a high-speed rotor-and-stator homogenizer. Further homogenize the emulsion for ten cycles at 20,000 PSI (138 MPa) using a high-pressure homogenizer to reduce the oil droplets to < 1 μm in diameter.
- Fill clean insulated containers with liquid nitrogen for SFL process.
- Spray and atomize the danazol feed solution and emulsions beneath liquid nitrogen surface at 5,000 psi (34.5 MPa) at a flow rate of 20 mL/min through a 127 μm ID PEEK nozzle measuring 15 cm in length by a syringe pump.
- Monitor and top up liquid nitrogen level in the container to ensure that the PEEK nozzle merged under liquid nitrogen level all the time.
- Collect the frozen material on a 150-mesh sieve or wait till the liquid nitrogen evaporated after the spray is completed.
- Lyophilize the collected frozen material using a tray lyophilizer equipped with a liquid nitrogen cold trap to condense DCM or ethyl acetate, of which the low melting points exceed the capture capacity of condenser. Maintain vacuum of 100 mTorr throughout the lyophilization cycle.
- Store the obtained dried powders under vacuum in the desiccator at room temperature.

Results

- Total drug/excipients concentrations of 5.75–7.5% were achieved in the emulsion formulations, compared to that of 0.55% in the cosolvent solution composition.
- XRD indicated that the lyophilized danazol SFL-solution composition and SFL-emulsion compositions were amorphous, even for SFL-emulsion compositions with high API-to-excipients ratio of 20:3.
- Surface areas increased with increasing drug and excipient concentrations, ranging from 8.9 m²/g of the SFL-solution composition to 83.1 m²/g of the SFL-emulsion compositions.
- Both danazol SFL-solution composition and SFL-emulsion compositions wetted and dissolved rapidly (100% in 2 min) than the slowly frozen counterpart and bulk danazol (50% in 2 min). Even for the SFL-emulsion compositions of high API-to-excipients ratios, > 90% of the danazol dissolved within 5 min. The SFL-emulsion compositions retained the high dissolution rates that achieved from SFL-solution composition.

High-potency formulations with high drug-to-excipient ratios and rapid dissolution rates would be advantageous in increasing dosages and in ameliorating side effects attributed to less excipients needed.

Example 6

The SFL and TFF particle engineering technologies were not only utilized to enhance dissolution rate of poorly water-soluble compounds but also used to enhance the stability of potentially labile compounds, such as proteins and peptides such as lactate dehydrogenase (LDH), and influenza vaccine (Yu et al. 2004; Engstrom et al. 2007a, b).

Due to the instability of proteins in solution, it is often necessary to produce a solid protein composition to achieve an acceptable shelf life. Ideally, the formulation should achieve high protein loadings with minimum burst release, high surface area, and submicron protein particles uniformly incorporated into 10–50 micron microspheres. However, it is challenging to produce stable submicron protein particles with surface area exceeding 10 m²/g, relative to less than 1 m²/g for lyophilized formulation (Engstrom et al. 2007a, b). It has been shown that the SFL process leads to less protein denaturation and subsequent aggregation relative to SFD since the destabilizing gas–liquid interfacial area is lower (Yu et al. 2006).

LDH is a fragile protein extensively studied. Producing stable high surface area submicron particles of LDH is of practical interest in protein storage and in various applications in controlled release. TFF process can also be used to produce stable submicron protein particle without loss of protein activity. Engstrom et al. reported LDH and lysozyme particles engineered by TFF process (Engstrom et al. 2008), with the detailed procedures described as following.

Method Capsule 6

Production of Highly Stable, Submicron Protein Particles by TFF

Based on the study reported by Engstrom et al. (2008)

Objective

- To produce highly stable, submicron LDH and lysozyme particles by TFF processing the aqueous solutions followed by lyophilization.

Equipment and Materials

- TFF apparatus
- Liquid nitrogen
- LDH, lysozyme, trehalose, and purified water
- Bench top tray lyophilizer
- Desiccator and desiccant
- Particle-size analyzer by laser light scattering
- BET apparatus

Method

- Prepare 0.25 mg/mL LDH in both 30 and 100 mg/mL trehalose solutions in 10 mM K_3PO_4 buffer with pH 7.5. Prepare 5 and 50 mg/mL aqueous solutions of lysozyme.
- Fill dry ice inside the hollow cylindrical stainless-steel drum. An equilibrium drum surface temperature of -50°C was achieved.
- TFF process of feed solutions: pass the protein feed solutions through a 17-gauge stainless-steel syringe needle at 4 mL/min to produce individual liquid droplets. The droplets fell from a height of 10 cm above a rotating stainless-steel cryogenic drum. Drum surface temperature was monitored by a moving surface temperature probe. Upon impacting, the droplets freeze simultaneously into round thin film disks.
- Collect the frozen thin disks into a 400-mL glass beaker filled with liquid nitrogen.
- Transfer the glass beakers containing the frozen disks of proteins to a -80°C freezer to evaporate excess liquid nitrogen.
- Cover the beakers with a single layer Kim-wipe to prevent particles exiting during drying, and transfer into a tray lyophilizer with precooled shelf temperature of -40°C . Primary drying was carried out at -40°C for 36 h at 300 mTorr and secondary drying at 25°C for 24 h at 100 mTorr.
- Upon completion of the lyophilization, purge the lyophilizer with nitrogen to release vacuum to minimize exposure of the protein powders to moisture in the ambient air.
- Rapidly transfer the dried powders to a dry box with humidity less than 15% RH, and package the powders into 20-mL scintillation vials. Purge vials with dry nitrogen gas for 2 min via a needle through the septa and an additional needle for the gas effluent.

Fig. 11.8 SEM of particles from 5 mg/mL lysozyme solutions processed by thin film freezing (TFF) at surface temperatures of -50°C (a) and processed by spray freeze into liquid nitrogen (SFL) (b). SEM of particles from 50 mg/mL lysozyme solution processed by TFF at surface temperatures of -50°C (c) and processed by SFL (d). Adapted from Engstrom, Lai et al. 2008 with permission from Springer

- Store the protein powders in glass vials at room temperature under vacuum in desiccator.

Results

- Protein particles with an average diameter of about 300 nm and 100% enzyme activity upon reconstitution (for LDH) were engineered by TFF process.
- The surface areas were significantly enlarged by TFF process, in the range of $30\text{--}75\text{ m}^2/\text{g}$. The higher the concentration of protein loading in the feed solution, the lesser the surface area of protein particles.

In TFF, the exposure of protein to the gas–liquid interface is minimized. The TFF-processed LDH composition was determined very high enzyme activities upon reconstitution, similar to that processed by direct lyophilization. TFF process has intermediate cooling rate (10^2 K/s), relative to that of the ultra-rapid cooling process SFD (10^6 K/s) and the slow process lyophilization (1 K/min), as shown in Fig. 11.8. Although the cooling rate of TFF is slower than that of SFL (10^3 K/s), it was sufficiently fast to arrest particle growth, whereas the relatively

minimized liquid–gas interfacial surface area in TFF process can improve protein stability by limiting the amount of protein adsorption to the interface, unfolding, and aggregation.

Later studies mainly focus on TFF-technology-engineered solid solutions/dispersions of poorly water-soluble drugs, such as tacrolimus, sirolimus, itraconazole, and repaglinide, to achieve supersaturated dissolution properties. Correlations between the enhanced *in vitro* properties of engineered drug compositions to improved *in vivo* performance in animal models were sought, as described in the following examples.

Example 7

Tacrolimus is a hydrophobic macrolide antibiotics used as a potent immunosuppressive agent, and has superior immunosuppressive effect compared to cyclosporine A. However, the erratic oral absorption profiles of tacrolimus have limited its therapeutic efficiency. It was reported that the oral bioavailability of tacrolimus ranges from 4 to 93% with a mean value of 25% (Wallemacq and Verbeeck 2001). Various innovative formulations and technologies have been used to improve the bioavailability of tacrolimus, with the theory that increasing the solubility greater than twofold through polymorphism can have a significant increase in biopharmaceutical activity. TFF technology was also employed to make engineered tacrolimus compositions with hydrophilic stabilizers (Overhoff et al. 2008), as described below.

Method Capsule 7

Preparation of Tacrolimus Solid Dispersions for Oral Delivery Using TFF

Based on the study reported by Overhoff et al. (2008)

Objective

- To investigate tacrolimus solid dispersions containing various stabilizers prepared by TFF process, and to determine the effect on their ability to form supersaturated solutions in aqueous media and on enhancing transport across biological membranes.

Equipment and Materials

- TFF apparatus
- Liquid nitrogen
- Tacrolimus (TAC), poly(vinyl alcohol (PVA), poloxamer 407 (P407), and sodium dodecyl sulfate (SDS)
- Bench-top tray lyophilizer

- Desiccator and desiccant
- Dissolution tester

Method

- Prepare feed solutions of TAC compositions by dissolving TAC and excipient(s) at 1:1 (w/w) ratio and 1.0% solid loading in a cosolvent acetonitrile/water (60/40, v/v), as listed in the table below.

| TAC/excipient(s) ratio (w/w) | Excipient(s) | Acetonitrile /water | Potency (%) | Solid loading (%) |
|------------------------------|----------------|---------------------|-------------|-------------------|
| 1:1 | SDS | 60/40 | 50 | 1.0 |
| 1:1 | PVA/P407 (1/1) | 60/40 | 50 | 1.0 |
| 1:1 | P407 | 60/40 | 50 | 1.0 |

- Apply the feed solutions to the rotating stainless-steel drum that pre-cooled to -150°C drop-wisely from a glass funnel tip 10 cm above the drum. The feed solution drops spread and form thin layer frozen disk simultaneously upon impacting on the drum.
- Place a metal pan filled with liquid nitrogen under the drum to collect and maintain the generated frozen material.
- Transfer immediately the frozen material into a bench-top tray lyophilizer with shelf pre-cooled to -60°C after evaporation of excessive liquid nitrogen in the collecting pan, and start lyophilization.
- Store the obtained dried powders of TAC compositions at room temperature under vacuum in the desiccator until characterization.

Results

- XRD indicated that the TFF-engineered TAC compositions were all amorphous.
- SEM displayed highly porous network of nanostructured aggregates of the TFF-engineered TAC compositions, in contrast to the plate-shaped crystalline bulk TAC with particle sizes ranging from a few microns to over $120\ \mu\text{m}$ in diameter.
- Supersaturation dissolution testing demonstrated the three TFF-engineered TAC compositions, as well as the commercial product Prograf[®] showed rapid dissolution reaching their maximum supersaturation within 2 h and achieved supersaturation relative to the solubility of bulk crystalline TAC. However, only the TFF-processed TAC/SDS = 1/1 composition had higher supersaturation than Prograf[®].

In this study, the selected stabilizers including partially hydrolyzed PVA which has been shown to increase drug concentration in vivo (Suzuki and Sunada 1998), P407 which has been shown to alter surface properties of crystals, and SDS which is a nonpolymeric anionic surfactant. SDS may be used to facilitate wetting and dissolution rates. TAC has good solubility in organic solvent and is readily dissolvable in the cosolvent.

Fig. 11.9 Mean whole blood absorption levels of tacrolimus compositions produced using the TFF process compared to Prograf[®]. Powders were given in gelatin capsule containing 1.5 mg equivalent tacrolimus (5 mg/kg) dosed via oral gavage to a rat model: TFF-processed tacrolimus/SDS (filled square), TFF-processed tacrolimus/PVA:P407 (filled triangle), TFF-processed tacrolimus/P407 (filled circle), Prograf[®] capsule powder (filled diamond). Reproduced from Overhoff, McConville et al. 2008 with permission from Springer

Single-dose pharmacokinetic study of orally administered TAC compositions in a rat model was conducted to determine the *in vivo* performance of the TFF-processed compositions. The results suggested that TFF-processed TAC/P407 = 1/1 achieved the greatest absorption with a 1.5-fold increase in AUC and higher C_{max} compared to Prograf[®]. All the TFF-engineered tacrolimus compositions had a shorter T_{max} compared to Prograf[®], as seen from Fig. 11.9. It is therefore concluded that the enhanced physico-chemical properties of TFF-engineered TAC compositions led to enhanced *in vivo* absorption over the current commercial product of TAC.

Example 8

Itraconazole is a broad-spectrum antimycotic triazole used for both prophylaxis and treatment of invasive fungal diseases for the last two decades. Itraconazole has pH-dependent solubility with extremely low value of approximately 1 ng/mL at neutral pH and approximately 4 μ g/mL at pH 1 (Peeters et al. 2002). Given the high log P value of 6.2, itraconazole is classified as a BCS class II drug (Amidon et al. 1995).

Sporanox® oral capsule is a currently available marketed oral dosage form of itraconazole. However, the oral absorption of ITZ in a subset of immunocompromised patients was not optimal, and the pharmacokinetics varied considerably among patients (Poirier et al. 1997). To treat invasive fungal infection, especially *Aspergillus* spp. infections, itraconazole levels of greater than 0.5 µg/g of lung tissue, or 0.5 µg/mL of blood, are required (Sobel 2000).

A novel composition containing itraconazole:mannitol:lecithin (1:0.5:0.2, w/w/w) for pulmonary delivery was made by TFF technology (Yang et al. 2008b). Here, we provide a step-by-step procedure for a standard batch of the itraconazole composition.

Method Capsule 8

Preparation of Amorphous Nanoparticulate Itraconazole Composition for Pulmonary Delivery Using TFF

Based on the study reported by Yang et al. (2008a, b)

Objective

- To develop amorphous nanoparticulate formulations of itraconazole for improved bioavailability following pulmonary administration.

Equipment and Materials

- TFF apparatus
- Liquid nitrogen
- Itraconazole, mannitol, lecithin, 1,4-dioxane, and purified water
- Bench-top tray lyophilizer
- Desiccator and desiccant

Method

- Prepare itraconazole feed solution: dissolve lecithin (118 mg) in 200 mL co-solvent of 1,4-dioxane and purified water (65/35, v/v); Subsequently dissolve itraconazole (588 mg) and mannitol (294 mg) to form a solution of 0.5% (w/v) solid loading with itraconazole: mannitol: lecithin=1:0.5:0.2 weight ratio.
- Precool the stainless-steel drum of TFF apparatus to -70 °C.
- Apply the feed solution to the cold drum of TFF apparatus from a glass funnel set 10 cm above the top surface of the rotating stainless-steel drum.
- Collect the generated frozen material in a container filled with liquid nitrogen.
- Transfer immediately the frozen material into a bench-top tray lyophilizer with shelf precooled to -20°C after evaporation of excessive liquid nitrogen, and start lyophilization.
- Store the lyophilized dry powder at room temperature in the desiccator under vacuum.

Results

- XRD and DSC confirmed that TFF-processed itraconazole:mannitol:lecithin = 1:0.5:0.2 was amorphous.
- SEM images showed the TFF-processed itraconazole composition has a highly porous structure with more regularly round-shaped particles in aggregated network.
- Aqueous colloidal dispersion of the TFF-processed itraconazole composition has a mean particle size of 230 nm.
- Dissolution testing revealed TFF-processed itraconazole composition achieved about five-times higher supersaturation than a crystalline Wet-milled itraconazole.

For comparison, a crystalline itraconazole nanoparticle composition was made by wet ball milling process (named Wet-milled itraconazole). SEM images showed that Wet-milled itraconazole was composed of fractured, irregular-shaped particles with various sizes, ranging from about 150 to 600 nm in length, as shown in Fig. 11.10a. In contrast, TFF-processed itraconazole composition exhibited a highly porous structure with more regularly round-shaped particles in aggregated network, as shown in Fig. 11.10b. Both the milling and TFF process dramatically reduced itraconazole particles to nanosize range compared to bulk micron-sized itraconazole particles shown in Fig. 11.10c.

Their corresponding mean particle size in aqueous dispersion was 230 and 570 nm, respectively. Dissolution testing revealed TFF-processed itraconazole composition achieved about 27-times higher supersaturation versus itraconazole equilibrium solubility, and 5 times higher dissolved itraconazole than the Wet-milled itraconazole, as seen from Fig. 11.11. (Yang et al. 2010).

A subsequent *in vivo* single-dose 24 h pharmacokinetic study of inhaled nebulized colloidal dispersions of the TFF-processed amorphous itraconazole composition and the crystalline Wet-milled itraconazole (equivalent to 20 mg itraconazole/mL) were conducted in a rat model. The results demonstrated a significantly higher systemic absorption and C_{\max} of itraconazole in blood of rats inhaled TFF-processed amorphous itraconazole composition than those inhaled crystalline Wet-milled itraconazole (Fig. 11.12a), although the lung depositions of itraconazole were comparable for both inhaled compositions (Fig. 11.12b). It is concluded from this study that using TFF technology to make amorphous nanoparticulate composition of poorly water-soluble drugs is an alternative and promising approach to overcome the low aqueous solubility issues by providing higher dissolution rate and apparent solubility, and subsequently higher bioavailability.

These examples are merely few representatives of the many poorly water-soluble drugs that contemplated by the cryogenic particle engineering technologies for enhanced dissolution properties and hence improved bioavailability.

TFF technology has been successfully used for cGMP manufacturing of stable amorphous drug products for clinical trial with improved patient compliance.

Data are presented as mean \pm SD. * p <0.05, ** p <0.01. Adapted from Yang, Johnston et al. 2010 with permission from Elsevier

11.5 Summary

Significant advances have been made in the past few decades toward understanding and tackling the poor bioavailability issues associated with poorly water-soluble drugs. Among various novel methods developed to improve dissolution properties for poorly water-soluble drugs, creation of amorphous pharmaceutical materials holds a lot of promise/demonstrated macroscopic performance advantages versus crystalline counterpart.

Cryogenic particle engineering technologies are “bottom-up” precipitation processes to generate amorphous nanostructured aggregates with significantly enlarged surface area, higher dissolution rates, and supersaturation, by rapidly inducing nucleation followed by particle growth arrest through stabilization via polymers and solidification of the solvent. The improved dissolution properties of poorly water-soluble drugs were achieved by (1) reducing particle size, thereby increasing surface area; (2) creating amorphous morphology; and (3) intimately mixing the drug with hydrophilic excipients. Moreover, without introducing mechanical force and heat, cryogenic processes are specifically suitable for thermal-labile drugs. Compared to SFD and SFL, TFF in particular has been shown to create stable amorphous compositions of poorly water-soluble drugs with significantly improved bioavailability and protein nanoparticles with high activity. Additionally, TFF process is more cost effective and scalable for manufacturing production.

By selecting proper excipient(s) and drug-to-excipient ratio in formulation and appropriate packaging and storage, cryogenic technologies can be used to manufacture stable amorphous drug dosage forms for diverse routes of administration, such as pulmonary, parenteral, and oral, with potentially reduced drug dose and side effects.

Chapter 12

Precipitation Technologies for Nanoparticle Production

Jasmine M. Rowe and Keith P. Johnston

Abstract Precipitation technologies have been widely studied for nanoparticle production because they provide more control over particle size, shape, and morphology as compared to mechanical processes, such as milling and homogenization. Several precipitation processes are discussed in this chapter, with special attention to experimental parameters and typical particle attributes. The chapter also touches on novel nanoparticle recovery techniques that may be coupled with precipitation processes to enable these precipitation technologies to be scaled for commercial applications.

12.1 Introduction

It has been reported that 40% or more of newly discovered drug candidates are poorly water soluble, often resulting in poor and/or erratic bioavailability (Lipinski 2001, 2002). Consequently, the majority of poorly water-soluble drugs fail to reach the market because their absorption into the body is limited by their slow dissolution rates in bodily fluids (Gardner et al. 2004; Rabinow 2004; Kipp 2004; Crison 2000). Traditional approaches to improving drug dissolution rates have focused on increasing the drug's solubility, often utilizing solubilizing excipients (CREMPHOR EL¹ (polyethoxylated castor oil) is added to TAXOL)², complexing

¹ CREMPHOR EL is a registered trademark of BASF Corporation.

² TAXOL (paclitaxel) is a registered trademark of Bristol-Myers Squibb Company.

agents (cyclodextrins and polyethylene glycols), or cosolvents (ethanol–water solvent mixtures) (Rabinow 2004; Kipp 2004; Muller et al. 2001). However, the success of these approaches has been limited due to the large quantities of excipients required to achieve sufficient solubilities, which increase the likelihood of adverse side effects in patients and limits drug loading (Rabinow 2004; Kipp 2004; Muller et al. 2001). For example, the marketed product SPORANOX IV³ requires 400 mg of 2-hydroxypropyl- β -cyclodextrin to solubilize 10 mg of the active ingredient, itraconazole (Sporanox Package Insert). Similar limitations impact the utilization of lipid-based formulations, which employ liposomes and emulsions to address solubility issues (Rabinow 2004). Solubilization of drugs using lipid-based methods leads to drug loadings well below 50% w/w (Matteucci et al. 2006) and often below ~10% w/w, especially for high-melting-point compounds, thus restricting their use in high-dose formulations (Rabinow 2004; Kipp 2004; Muller et al. 2001). Consequently, only a small number of commercialized pharmaceutical products are based on these strategies (Muller et al. 2001).

An alternative approach to enhancing the dissolution rates of poorly water-soluble drugs has been to formulate the drugs as nanoparticles, loosely defined in the pharmaceutical industry as structures with a diameter less than 1 μm . According to the Noyes–Whitney equation, which is based on Fick’s first law of diffusion, dissolution rates of drug particles may be enhanced by increasing the drug’s solubility in aqueous media (C_{Eq}) and/or by reducing particle size, which increases the surface area for adsorption (A) and decreases the boundary layer thickness (h) (Noyes and Whitney 1897):

$$\frac{\partial M}{\partial t} = \frac{DA}{h}(C_{\text{Eq}} - C_{\text{Bulk}}), \quad (12.1)$$

where M is the mass of undissolved drug, t is the time, D is the average diffusion coefficient, and C_{Bulk} is the drug concentration in the bulk solution. Nanoparticle formulations offer several advantages over lipid-based solubilization methods for improving drug dissolution rates. Unlike lipid-based techniques, particle formation processes are more amenable to compounds that have low solubility in both water and oils, which is often the case for high-energy crystals (Rabinow 2004). Additionally, by circumventing the need to deliver a dissolved compound, the drug’s preferred crystalline state may be preserved during delivery and storage (Rabinow 2004). Furthermore, solid nanoparticles facilitate higher drug loadings than solubilized formulations, which is crucial for high-dose compounds.

Nanoparticles may be produced by top-down or bottom-up approaches. Top-down approaches refer to mechanical processes, such as milling and homogenization, and use high-impact forces to break large particles into smaller particles. Particles with median diameters of 300–400 nm are commonly produced by these methods, and particles smaller than 200 nm have been reported for the poorly water-soluble drugs danazol (average particle diameter of 169 nm) (Liversidge and Cundy

³ SPORANOX IV is a registered trademark of Janssen Pharmaceutical Products, LP.

1995) and atovaquone (average particle diameter of 100 nm) (Dearn 1994; Westesen and Siekmann 1998) using top-down methods. However, the high-energy inputs required to achieve these levels of size reduction may subject the drug to chemical degradation, often through thermal degradation, due to the considerable amount of heat that is often generated during milling and homogenization processes (Jacobs et al. 2000; Liversidge et al. 2003; Muller and Bohm 1997). These high-energy methods are also prone to producing partially amorphous drug domains, complicating control of crystalline morphology, and thus drug stability (Chan and Chew 2003). Moreover, these methods often require lengthy processing times, risk contamination with impurities, and are subject to low process yields (Muller et al. 2001). In contrast, bottom-up approaches refer to solution-based precipitation techniques that induce phase separation of the drug (originally in solution) from the solvent. Precipitation is driven by a deviation from phase equilibrium conditions, where typical supersaturation driving forces are gradients in concentration or temperature. This chapter will focus on precipitation processes where supersaturation of a drug solution produces nucleation and growth under controlled conditions to influence particle formation. Supersaturation, S , is defined as the solute concentration (C_{drug}) relative to that under equilibrium conditions ($S = C_{\text{drug}}/C_{\text{eq}}$). Freezing-induced nanoparticle precipitation methods (based on a thermal driving force) are discussed in detail in review articles by Overhoff et al. (2007a, 2009).

In non-freezing-based precipitation techniques, the poorly water-soluble drug is typically dissolved in a solvent and precipitation of the drug is initiated by a reduction in solvent power, by either addition of an antisolvent or solvent evaporation. A reduction in solvent powder leads to supersaturation of the drug and drives nucleation of drug particles. Once nucleation occurs, the particles grow by condensation, in which dissolved drug molecules diffuse to the particle surface and integrate into a solid particle, and/or by coagulation, where multiple particles collide and aggregate to form larger particles (Fig. 12.1) (Weber and Thies 2002). Stabilizers may be added to the system to arrest particle growth.

Particle nucleation and growth are competing processes. The degree of supersaturation, S , significantly impacts nucleation rates, as seen in the equation describing primary nucleation rate, B^0 (Sohnel and Garside 1992)

$$B^0 \propto \exp\left(-\frac{16\pi\gamma^3V_M^2N_A}{3(RT)^3[\ln(1+S)]^2}\right), \quad (12.2)$$

where γ is the interfacial tension, V_M is the molar volume, N_A is Avogadro's number, R is the ideal gas law constant, and T is the temperature. According to (12.2), nucleation rates increase as the degree of supersaturation increases. However, supersaturation levels decrease as particles grow by condensation, due to a reduction in the solute mass in solution. Hence, condensation competes with nucleation. Furthermore, coagulation competes with condensation by reducing the total number of particles, and thus surface area, in the system (Matteucci et al. 2006). Therefore, final particle properties, including size distribution and morphology, are heavily

Fig. 12.1 Mechanism of precipitation. Adapted from Weber and Thies (2002)

impacted by the processing parameters that influence nucleation and growth rates (e.g., solvent choice, stabilizer selection, and mixing rates). Rapid generation of supersaturation over a narrow time interval facilitates more narrow PSDs. Therefore, faster nucleation rates, relative to growth, favor the production of uniformly smaller particles.

Relative to top-down approaches (milling and homogenization processes), precipitation technologies are typically more controlled, in terms of consistently producing particles with similar morphologies, and offer the ability to achieve higher drug loadings (Matteucci et al. 2006, 2007; Overhoff et al. 2007a, b; Engstrom et al. 2007, 2008; Rasenack and Muller 2002; Rogers et al. 2004; Shoyele and Cawthorne 2006; Vaughn et al. 2005; Young et al. 2000). Precipitation processes are often easier to scale-up and require less particle handling than milling and homogenization operations, resulting in higher process yields and lower impurity risks, as well as simplified cleaning and sterilization procedures (Rogers et al. 2001a). Additionally, precipitation technologies may be operated as continuous or semicontinuous processes, whereas milling and homogenization operations are batch processes (Rogers et al. 2001a). This chapter will focus on several different approaches to nanoparticle precipitation that are relevant to pharmaceutical drug development, highlighting key advances and important processing parameters for various active pharmaceutical ingredients (API). Precipitation processes utilizing compressed or supercritical fluids, as well as aqueous media, as antisolvents, will be summarized. Furthermore, novel modifications to conventional precipitation processes will be discussed, in addition to several techniques that have been used to harvest the resultant nanoparticles after precipitation, including flocculation-based processes.

12.2 Precipitation Processes Utilizing Compressed or Supercritical Fluids

Compressed fluid and supercritical fluid (SCF) antisolvent precipitation processes offer several advantages over more conventional liquid antisolvent processes. The antisolvent may be completely removed via pressure reduction to the gaseous phase, resulting in improved product purities and reduced environmental and toxicity concerns. A SCF is a fluid that has been compressed beyond its critical pressure (P_c) or heated above its critical temperature (T_c). An important feature of SCFs is that their densities can change significantly with small changes in pressure. These density changes give rise to variations in diffusivity and viscosity, as well as the solubility of other solvents and small solutes. Typical diffusivities of SCFs are on the order of 10^{-3} cm²/s (~100 times greater than that for liquids) and their viscosities are on the order of 10^{-4} g/cm/s (~100 times lower than that for liquids). These favorable mass transfer properties facilitate rapid diffusion of the SCF antisolvent into a liquid solvent, which enables rapid supersaturation and nucleation, thus favoring the production of small particles.

Several commonly used SCFs are listed in Table 12.1 (Sekhon 2010). Of these fluids, carbon dioxide (CO₂) is the most prevalently used in pharmaceutical applications because it is inexpensive, nonflammable, and nontoxic. Figure 12.2 shows how small changes in pressure and temperature result in significant changes in the density of CO₂, which in turn, largely affects the solubility of small molecules in CO₂ (Fig. 12.3). The density of CO₂, as a function of pressure (P) and temperature (T), may be obtained from the NIST Standard Reference Database (<http://webbook.nist.gov>) or calculated as follows (Jouyban et al. 2002):

$$\rho_{\text{CO}_2} = \frac{1}{44} \exp\left(-27.091 + 0.609\sqrt{T} + \frac{3966.170}{T} - \frac{3.445P}{T} + 0.401\sqrt{P}\right), \quad (12.3)$$

where ρ_{CO_2} is in moles/mL, T is in Kelvin, and P is in bars.

Table 12.1 Critical constants for select supercritical fluids (SCF)

| SCF | T_c (°C) | P_c (bar) | Safety hazard |
|--------------------------------------|------------|-------------|--|
| Trifluoromethane (fluoroform) | 25.9 | 47.5 | |
| Chlorotrifluoromethane | 28.9 | 39.2 | |
| Ethane | 32.3 | 48.8 | Flammable gas |
| Carbon dioxide | 31.1 | 73.7 | |
| Dinitrogen monoxide (laughing gas) | 36.5 | 72.6 | May enhance combustion of other substances |
| Sulfur hexafluoride | 45.5 | 37.6 | |
| Chlorodifluoromethane (HCFC 22; R22) | 96.4 | 49.1 | Combustible under certain conditions |
| Propane | 96.8 | 43.0 | Extremely flammable |
| Ammonia | 132.4 | 112.7 | Flammable and toxic |
| Trichlorofluoromethane (CFC 11; R11) | 198.0 | 44.1 | |
| Water | 374.0 | 220.5 | |

Fig. 12.3 Solubility of several drug compounds in CO₂ at varying pressures and temperatures. Data adapted from Gupta (2006)

In addition to CO₂ density, a drug's solubility in supercritical CO₂ (scCO₂) is dependent upon the drug's vapor pressure and drug–CO₂ interaction. The following empirical correlation for drug solubility in CO₂ was developed by Mendez-Santiago and Teja (1999):

$$\gamma_2 = \frac{10^6}{P} \exp\left(\frac{A}{T} + \frac{B\rho_1}{T} + C\right), \quad (12.4)$$

where γ_2 is in $\mu\text{mol/mol}$, P is in bars, T is in Kelvin, ρ_1 is the CO₂ density in mols/mL, and the constants A , B , and C are empirical constants (values for various drug molecules are listed in Table 12.2). Accurate knowledge of a drug's solubility in CO₂ is necessary to reliably produce adequate process yields.

SCF precipitation techniques fall into three major categories (1) gas antisolvent precipitation (GAS), (2) precipitation with a compressed antisolvent (PCA), and (3) rapid expansion from supercritical solutions (RESS). PCA processes are also commonly referred to as aerosol solvent extraction system (ASES), solution-enhanced dispersion by supercritical fluids (SEDS), and supercritical antisolvent (SAS). The differences between these different precipitation techniques are discussed in the following sections of this chapter.

12.2.1 Precipitation with a Gaseous Antisolvent (GAS)

GAS precipitation is a batch process, in which the SCF antisolvent, often CO₂, is added to an organic solution containing dissolved API. Typical operating pressures for this process are 5–8 MPa, in the range where CO₂ is highly soluble in most organic solvents (Martin and Cocero 2008). As the CO₂ dissolves into the solute-rich liquid phase, the solvent strength decreases. Consequently, the API's solubility in the solvent decreases, which generates supersaturation of the API and promotes nucleation and precipitation. In some cases, additional excipients may also be dissolved in the organic drug solution to precipitate the API within an excipient matrix. In order to induce rapid drug nucleation, which favors the production of small particles, CO₂ must be readily soluble in the organic solvent and the API must have low solubility in CO₂. Excessive solubility of the API in CO₂ would facilitate particle growth. Under optimal operating conditions, CO₂'s high solubility and favorable transport properties in the organic solvent facilitate homogenous supersaturation conditions more rapidly than can be achieved using liquid antisolvents. When precipitation is complete, the CO₂–organic solvent solution is flushed from the system and the precipitate, i.e., the drug powder, remains in the precipitation vessel. The drug powder may then be washed with fresh CO₂ to remove excess organic solvent. A schematic of the GAS precipitation system is shown in Fig. 12.4. The primary drawback of the GAS precipitation process is the difficulty in harvesting the precipitate drug particles from the organic solvent solution while minimizing particle growth and agglomeration.

Table 12.2 Values of empirical constants used to determine drug solubility in CO₂ using (12.4)

| Drug | <i>A</i> | <i>B</i> | <i>C</i> |
|-----------------------------|----------|----------|----------|

Data from Gupta (2006)

Furthermore, in cases where elevated temperatures are need to sufficiently expand the SCF into the organic solvent, thermal degradation of the API may occur.

Fig. 12.4 Schematic of GAS process. Schematic adapted from Martin and Cocero (2008)

Because GAS precipitation is driven by the antisolvent capabilities of CO₂ in the organic solution, appropriate processing conditions may be selected based on optimizing thermodynamic criteria, specifically by understanding the volumetric expansion of the organic solvent due to CO₂ solubilization, and thus solubility of the solute in the solvent–CO₂ mixture. In a study by de la Fuente et al., volumetric expansion of the organic solvent was correlated to the difference between the partial molar volumes (v) of the organic solvent under operating conditions versus atmospheric pressure, as shown in the following equation (de la Fuente Badilla et al. 2000):

$$\frac{\Delta v}{v} = \frac{v(T, P) - v_0(T, P_0)}{v_0(T, P_0)}, \quad (12.5)$$

where T is the operating system's temperature, P_0 is the atmospheric pressure, and v_0 is the partial molar volume at the operating system's temperature and atmospheric pressure. Studies have shown that (12.5) adequately predicts drug solubilities in a solvent–CO₂ solution for naphthalene and phenanthrene in a toluene–CO₂ system, and thus is capable of predicting their success in forming satisfactory particles by GAS precipitation (Fig. 12.5) (Martin and Cocero 2008; de la Fuente Badilla et al. 2000; de la Fuente et al. 2004). The likelihood of a specific solute to successfully form small, uniform particles by GAS precipitation is indicated by a steep decrease in its solubility at some CO₂ concentration. More specifically, a high sensitivity of the solute's solubility to CO₂ concentration indicates that precipitation will occur rapidly and homogeneously once a critical concentration is reached. On the other hand, systems that demonstrate only a slow decrease in solubility as CO₂ concentration is increased will likely not yield small, uniform particles, as precipitation will take place continuously as CO₂ is fed into the precipitation vessel. de la Fuente

Fig. 12.5 Relative volumetric expansion of toluene, defined as the difference between the partial molar volumes (v) of toluene under operating and atmospheric conditions, and solute solubility in a (a) CO_2 -toluene-naphthalene and (b) CO_2 -toluene-phenanthrene system. et al. hypothesized that optimum GAS precipitation conditions exist at the minimum of the solvent's volumetric expansion curve, as defined in (12.5). According to Fig. 12.5, naphthalene was predicted to be successfully precipitated using the GAS technique while phenanthrene was not (de la Fuente Badilla et al. 2000). This model has also been verified experimentally for a salicylic acid-propanol- CO_2 system (Shariati and Peters 2002).

Typical particle sizes of poorly water-soluble drugs prepared by GAS precipitation are on the order of 1–10 μm (Martin and Cocero 2008), although submicron particle sizes have been achieved in some cases (Turk 2009). GAS precipitation processes have also been reported to be successfully scaled from a 300-mL to 1-L batch size (Muhrrer et al. 2003; Muhrrer and Mazzotti 2003). However, when processes are scaled to larger volumes, a stirrer was needed to improve mixing between the organic solvent and CO_2 (Martin and Cocero 2008). Key process parameters that control final particle size and morphology include the pressure and temperature of the precipitation process, solvent selection, and the CO_2 addition rate to the organic solution (Muhrrer et al. 2003; Fusaro et al. 2004; Subramaniam et al. 1997; Mueller et al. 2000). As mentioned previously, changes in pressure and temperature largely influence the mass transfer properties of CO_2 . Solvent selection and the rate of CO_2 addition affect supersaturation levels and, thus, nucleation and crystallization rates. In a study by Muller et al., GAS precipitation of a proprietary poorly water-soluble drug yielded amorphous spheres when precipitated from ethanol, whereas a crystalline form was obtained when acetone or acetonitrile was chosen as the solvent, even though all other operating conditions were identical (Mueller et al. 2000).

Additional studies by Muller et al. reported that the average particle size of that poorly water-soluble drug, when precipitated from an ethanol solution, could be reproducibly adjusted to sizes between ~ 200 nm and $10 \mu\text{m}$ by varying the addition rate of CO_2 over two orders of magnitude (Muhrer et al. 2003; Mueller et al. 2000). The CO_2 addition rate (Q_A) was defined as the ratio between the CO_2 flow rate and the initial volume of organic solution, in order to normalize for different batch sizes. Moreover, the particle-size distribution (PSD) was unimodal for “slow” ($Q_A \leq 0.04 \text{ min}^{-1}$) and “fast” ($Q_A \geq 1.54 \text{ min}^{-1}$) CO_2 addition rates, but was bimodal for “intermediate” addition rates ($0.1 \leq Q_A \leq 0.5 \text{ min}^{-1}$) (Muhrer et al. 2003). In another example where paracetamol (aqueous solubility $\sim 12 \text{ mg/mL}$) was precipitated from an acetone solution by GAS, the mean particle size decreased threefold ($250\text{--}87 \mu\text{m}$) with an increase in Q_A by a factor of three ($0.1\text{--}3.33 \text{ min}^{-1}$) (Fusaro et al. 2004). In contrast, GAS precipitation of lysozyme from dimethyl sulfoxide (DMSO) did not demonstrate a significant change in particle size with varying CO_2 addition rates (Muhrer and Mazzotti 2003). Additionally, for the studies using paracetamol and lysozyme, a unimodal PSD was obtained regardless of Q_A , which was varied from “slow” to “fast” (Fusaro et al. 2004; Muhrer and Mazzotti 2003).

In light of these conflicting reports relating experimental parameters to final particle properties, a better understanding of the GAS process, specifically the sensitivity of CO_2 addition rates on resultant particle size, has been sought through the development of theoretical models to describe the GAS process. Muhrer et al. presented a model that couples population balance theory with thermodynamic equilibrium to relate nucleation rates to final particle size (Muhrer et al. 2002). Solution thermodynamics and particle formation and growth are accounted in the model based on assumptions of isothermal conditions and instantaneous vapor–liquid phase equilibrium upon addition of the antisolvent, thus neglecting any mass transfer resistance. Particle growth, however, is described by an empirical correlation, which does not discern between the different mechanisms of condensation and coagulation (Martin and Cocero 2008; Dodds et al. 2007).

In the Muhrer et al. model, systems in which primary nucleation (generation of nuclei resulting from supersaturation, in the absence of drug crystals) is dominant to secondary nucleation (occurs in the presence of existing drug crystals) tend to be more susceptible to variations in CO_2 addition rates. Therefore, in systems dominated by primary nucleation, average particle sizes and PSDs may be tuned by controlling CO_2 addition rates. An increase in Q_A elevates supersaturation levels, facilitating higher nucleation rates and thus promoting the formation of more nuclei, which results in a larger population of smaller particles. The relationship, as determined by Muhrer’s model (Muhrer et al. 2002), between supersaturation ratio, S , and average particle size, as a function of Q_A , is illustrated in Fig. 12.6. The supersaturation ratio was calculated as the ratio of the fugacity of the solute in the liquid phase to the fugacity of the pure solid. Muhrer’s model also demonstrated that in cases where secondary nucleation is dominant, the mean particle size is largely unaffected by changes in the rate of CO_2 addition, whereas systems with intermediate secondary nucleation rates were predicted to be moderately affected by variations in Q_A and possessed bimodal distributions.

Fig. 12.6 Effect of CO_2 addition rate, Q_A , on the supersaturation ratio, S , and the average size of particles produced by GAS precipitation for a model phenanthrene–toluene– CO_2 system. Reprinted with permission from Fusaro et al. (2005). Copyright (2005) American Chemical Society

Good quantitative agreement with this model was obtained in two studies where phenanthrene was micronized using GAS precipitation (Muhler et al. 2002; Bakhbakhi et al. 2005). However, because this model was developed primarily to explain the effect of Q_A on final particle size, minor deviations between the model and experimental results were observed when examining the role of initial drug concentration on particle size for a poorly water-soluble drug–ethanol– CO_2 system. The discrepancies were attributed to the fact that the model neglects mass-transfer resistances, and thus did not account for the increasing viscosity of the organic solution due to higher drug concentration. In response, Elvassore proposed a population balance model that accounted for particle nucleation, growth, aggregation, as well as settling, where nucleation and growth were described by the McCabe model (Elvassore et al. 2003, 2004). The model was validated with experimental measurements for the GAS precipitation of poly(L-lactide) acid (PLLA). While a good correlation was achieved, several model parameters could not be experimentally determined and were assumed in order to fit the model to the experimental data. The results of this model indicated that aggregation rates should not be neglected and that they strongly influence the attainment of unimodal (low aggregation rates) versus bimodal (high aggregation rates) distributions, in contrast to Muhler’s model which did not account for aggregation rates. Dodds et al. developed another model that used solution thermodynamics and crystallization kinetics to examine particle growth in GAS processes (Dodds et al. 2007). The Dodds et al. model showed good agreement with experimental

results for GAS precipitation of naphthalene, phenanthrene, cholesterol, and beclomethasone dipropionate (Dodds et al. 2007). While all of the models contributed to an enhanced understanding of the underlying mechanisms driving GAS precipitation, further validation is required to understand their applicability to additional drug–solvent systems. It should be noted that predicting physical properties of particles produced by GAS precipitation has not been trivial and currently appears to be highly dependent on a specific system due to the complexities that arise from multiple interactions within the system (drug–solvent, solvent–CO₂, and drug–solvent/CO₂ solution). It is also important to note that GAS precipitation generally does not produce nanoparticles, as it is typically limited by the mixing and thus nucleation rates that can be achieved in this system.

12.2.2 Precipitation with a Compressed Liquid or Supercritical Fluid (PCA, ASES, SEDS, and SAS)

The physical properties of drug powders produced by precipitation methods are greatly influenced by the process arrangement. In contrast to GAS precipitation, the PCA process atomizes the drug solution into the SCF antisolvent. In PCA, the organic solution containing the API is atomized into a vessel that has been pressurized with the compressed liquid or SCF, often CO₂. Unlike the batch GAS process, PCA is a semicontinuous technique because the scCO₂ is continuously fed throughout the atomization process to promote more rapid mixing with the organic solvent. Upon removal of the residual solvent, the pressure in the vessel is reduced to atmospheric pressure and the drug particles are collected by a filter at the bottom of the vessel. Similar to the GAS process, additional excipients may also be dissolved in the organic drug solution to produce composite API/excipient particles. A schematic of the PCA system is shown in Fig. 12.7. The PCA process typically operates at 9–15 MPa, slightly higher than GAS processes, in order to achieve higher supersaturation values and sufficient mixing between the CO₂ and organic solution feed streams (Martin and Cocero 2008).

Atomization of the drug–CO₂ solution into the antisolvent, as opposed to bubbling the CO₂ solution, facilitates more rapid mass transfer between the drug solution and the antisolvent, which makes the PCA process more conducive to the production of smaller particles compared to GAS precipitation (Rogers et al. 2001a; Martin and Cocero 2008; Fusaro et al. 2004). The high surface area of atomized droplets increases the area of intimate contact between the drug solution and the antisolvent to facilitate mixing, thus promoting rapid supersaturation and precipitation. Upon atomization, the organic solvent diffuses into the CO₂ phase and the CO₂ diffuses into the organic droplets, resulting in a more efficient, bidirectional mass transfer of CO₂ and organic phase, in contrast to the unidirectional mass transfer in GAS precipitation (Rogers et al. 2001a; Martin and Cocero 2008).

Fig. 12.7 Schematic of PCA process. Reprinted with permission from Martin and Cocero (2008). Copyright 2008 with permission from Elsevier

The mass-transfer efficiency between the CO₂ and organic solvent phase may be further increased by adjusting operating parameters of the PCA process, including increasing the miscibility between the solvent and CO₂ or by tuning the degree of atomization of the organic solution into the CO₂ phase. Increased miscibility between the solvent and CO₂ and more intense atomization, which yields higher surface area droplets, enhance mass-transfer efficiency (Rogers et al. 2001a; Fusaro et al. 2004). For systems in which the solvent and CO₂ are fully miscible (supercritical conditions), experimental parameters that affect mixing rates between the solvent and CO₂ streams, such as degree of atomization, are less likely to influence precipitation results for some nozzle designs, thus suggesting that mixing rates between the solvent and CO₂ are faster than precipitation rates (Reverchon et al. 2003a, b, 2007). However, for systems where solvent and antisolvent are only partially miscible (subcritical conditions), mixing parameters significantly influence precipitation results. Furthermore, changes in particle morphology, as well as an increased propensity for particle agglomeration, are frequently observed at subcritical conditions, indicating that mixing of the CO₂ and solvent is not complete and occurs simultaneously with precipitation during droplet formation (Martin and Cocero 2008). An increase in atomization intensity facilitates solvent–CO₂ mixing during droplet formation. For subcritical conditions, the degree of atomization may be quantified by the Weber number, N_{we} , a dimensionless ratio of inertial to surface tension forces, which is given by

$$N_{we} = (\rho_A v^2 D_{\text{drop}}) / \sigma, \quad (12.6)$$

where ρ_A is the antisolvent density, v is the relative velocity, D_{drop} is the droplet diameter, and σ is the interfacial tension. Higher-intensity atomization is characterized by larger N_{we} values for a given Reynolds number (Re) (Lengsfeld et al. 2000).

Fig. 12.8 Schematics of different nozzles used in SCF precipitation processes: (a) coaxial nozzle (Okamoto and Danjo 2008), (b) coaxial nozzle with a converging–diverging annulus (Fusaro et al. 2005), and (c, d) two configurations for a two-component jet nozzle (Fusaro et al. 2005; Jarmer et al. 2003). Reprinted with permission from Okamoto and Danjo (2008) (Copyright 2008 with permission from Elsevier), Fusaro et al. (2005) (Copyright 2005 American Chemical Society), and Jarmer et al. (2003) (Copyright 2003 with permission from Elsevier)

However, for supercritical conditions, the surface tension of the organic solvent decreases to zero over a distance shorter than that of characteristic jet break-up lengths, calculated based on classic jet break-up theory (Lengsfeld et al. 2000). Thus, distinct droplets do not form and the solvent stream forms more of a gaseous plume (Bristow et al. 2001). Therefore, atomization for miscible fluids were analyzed using gaseous mixing theory and mixing rates, using mixing length scales for turbulent mixing (Shekunov et al. 1999; Jarmer et al. 2003).

Atomization intensity may be increased using ultrasonic dispersion devices, coaxial nozzles, or two-component jet nozzles to enhance the interaction between the solvent and antisolvent in a mixing chamber prior to atomization. Schematics of different nozzle types are shown in Fig. 12.8. Ultrasonic dispersion devices vibrate at an ultrasonic frequency to enhance mass-transfer efficiency by increasing mixing rates between the solvent and antisolvent, as well as to atomize the feed solution into smaller droplets. Final particle sizes may be tuned by controlling vibration intensity of the dispersion device. For coaxial (or two-fluid) nozzles (Fig. 12.8a), the organic drug solution is fed through one axis and the scCO_2 is fed through the other. As the two feeds meet, intense mixing of the two streams facilitates rapid nucleation and particle precipitation upon atomization from the nozzle. Primary particle sizes may be controlled by adjusting the relative velocities of the two streams, which regulates the intensity of mixing between the solvent and antisolvent phase. Several configurations for coaxial nozzles have been utilized, with optimal designs heavily dependent on the particular drug system. In some cases, a converging–diverging nozzle is employed to rapidly disperse the liquid feed during atomization to facilitate nanoparticle production (Fig. 12.8b). In two-component jet nozzles, the antisolvent is introduced at a sharp angle into the mixing chamber to enhance turbulence of the fluids during mixing (Fig. 12.8c, d). Studies have shown that turbulent mixing of the solvent and antisolvent greatly impacts supersaturation homogeneity, allowing for more control of the PSD during PCA by tuning precipitation kinetics (nucleation

and growth rates) (Jarmer et al. 2003). Primary particle sizes ranging from 200 to 1,000 nm for poorly water-soluble drugs, and as low as 50 nm for water-soluble molecules, have been achieved using these technologies (Table 12.3) (Gupta 2006).

Scalability of the PCA technology has been demonstrated for the production of paracetamol particles at laboratory scales ($1-8 \times 10^{-4}$ kg/s CO_2 + ethanol + paracetamol flowrates) to small manufacturing plant scales ($0.9-1.5 \times 10^{-2}$ kg/s CO_2 + ethanol + paracetamol flowrates) (Baldyga et al. 2010). In terms of batch sizes, 1 kg nanoparticles/day have been produced at pilot plant scale using PCA (Gupta 2006). However, it is important to note that strategies for scaling up PCA processes differ when operating under subcritical or supercritical regimes. Subcritical operating conditions exhibit higher sensitivities to certain parameters, such as nozzle design. PCA precipitation of PLLA at both laboratory and pilot plant scales, under conditions of partial solubility of CO_2 in the solvent, was heavily influenced by nozzle design. While PCA processes operating at higher Re are more likely to be successfully scaled up, maintenance of a constant Re or constant jet velocities at the anti-solvent inlet does not guarantee scalability between laboratory and pilot plant batches (Jarmer et al. 2006). One criterion that enables process scalability is the maintenance of a constant energy dissipation rate in the nozzle. Nozzle design significantly influences the propagation of secondary nucleation mechanisms, and thus impacts energy dissipation rates during solvent atomization. Another option to achieve scalability is to target a constant suspension density and residence time within the mixing chamber by adjusting solvent flow rates through the nozzle, which maintains mixing quality and, thus, promotes comparable nucleation and growth rates. When either of these conditions was met, PLLA particles with similar PSDs were obtained at both laboratory and pilot scales of production (Martin and Cocero 2008; Jarmer et al. 2006). When operating in the complete miscibility regime, PCA precipitation of amoxicillin conducted at both laboratory and pilot plant scales yielded very similar results, in terms of particle size and morphology, regardless of nozzle design and residence time in the precipitation vessel (Martin and Cocero 2008; Reverchon et al. 2003b). The same trends were observed in a study by Wubbolts et al., where acetaminophen and ascorbic acid particles were produced by PCA under subcritical versus supercritical conditions (Wubbolts et al. 1999). When an acetaminophen–ethanol solution was atomized into CO_2 under subcritical conditions, the droplets did not fully evaporate and a solvent-rich region was observed at the bottom of the precipitation vessel. This subcritical operating condition resulted in $\sim 200\text{-}\mu\text{m}$ acetaminophen particles. The large particle sizes were attributed to the growth of nucleated crystals in the solvent-rich phase at the bottom of the vessel. In contrast, an ascorbic acid–ethanol– CO_2 system under supercritical conditions yielded $\sim 1\text{-}5\text{-}\mu\text{m}$ particles, in which particle size was virtually insensitive to temperature and pressure changes while in the supercritical regime.

Reverchon et al. further investigated the span of particle properties produced by PCA when operating under supercritical conditions (Reverchon et al. 2007). More than 20 compounds, spanning a wide range of materials including superconductor and catalyst precursors, dye pigments, polymers, and pharmaceuticals, were

Table 12.3 Drug nanoparticles produced by PCA

| Drug | Solvent | P (bar) | T (K) | Atomization conditions | Particle size (nm) |
|--|---------------------|---------|---------|--------------------------------------|--------------------|
| Albumin (Bustami et al. 2000) | Water/ethanol | N/A | N/A | Coaxial nozzle | 50–500 |
| Amoxicillin (Reverchon et al. 2000, 2003b; Reverchon and Della Porta 1999) | N-Methylpyrrolidone | 150 | 313 | Coaxial nozzle with coaxial injector | 120–1,200 |
| Gentamicin/PLA (Falk et al. 1997) | Methylene chloride | 85 | 308 | US nozzle, vibrating at 120 kHz | 200–1,000 |
| Hydrocortisone (Weber et al. 1999) | Dimethyl sulfoxide | 100 | 308 | | 600 |
| Ibuprofen (Weber et al. 1999) | Dimethyl sulfoxide | 100 | 308 | | 500–1,000 |
| Insulin (Bustami et al. 2000) | Water/ethanol | | | Coaxial nozzle | 50–500 |
| Naltrexen/l-PLA (Weber et al. 1999) | Methylene chloride | 85 | 308 | US nozzle, vibrating at 120 kHz | 200–1,000 |
| Nicotinic acid (Falk et al. 1997) | Ethanol | | | Coaxial nozzle | 400–750 |
| RhDNase (Hanna and York 1998) | Ethanol | | | Coaxial nozzle | 50–500 |
| Salbutamol (Bustami et al. 2000) | Methanol/acetone | 100 | 333 | Coaxial nozzle | 500 |
| Naloxone/l-PLA (Hanna and York 1998) | Methylene chloride | 85 | 308 | US nozzle, vibrating at 120 kHz | 200–1,000 |
| Dexamethasone phosphate (Falk et al. 1997) | Methanol | 102 | 313 | US nozzle, power=90 W | 175 |
| Griseofulvin (Thote and Gupta 2005) | Dichloromethane | 96.5 | 308 | US nozzle, power=90–180 W | 310–510 |
| Griseofulvin (Chattopadhyay and Gupta 2001a) | Tetrahydrofuran | 96.5 | 308 | US nozzle, power=120–180 W | 200–280 |
| Lysozyme (Chattopadhyay and Gupta 2001a) | Dimethyl sulfoxide | 96.5 | 310 | US nozzle, power=12–90 W | 190–730 |
| Lysozyme (Rodrigues et al. 2009) | Ethanol | 180–250 | 318–333 | Coaxial nozzle | 100–5,000 |

examined in this study (Reverchon et al. 2007). Nanoparticles were formed only under supercritical conditions and when the solute was virtually insoluble in the antisolvent–solvent mixture. In agreement with previous studies, particle size was not dependent on nozzle design for these experiments, which were operated at supercritical conditions (Martin and Cocero 2008; Reverchon et al. 2003a, b; Wubbolts et al. 1999). However, the initial solute concentration in the organic solvent did influence final particle size. Increased concentrations of the solute in the organic solvent resulted in larger particles (Reverchon et al. 2007). In fact, Fig. 12.9 shows that, for the entire range of compounds that were tested, average particle sizes scaled linearly with the relative concentration of solute in the feed organic solvent, C_R , for a given operating temperature, pressure, and mole fraction of antisolvent, where $C_R = C_{\text{drug}}/C_{\text{eq}}$ and C_{drug} is the concentration of solute in the organic solvent. This linear relationship between feed drug concentration and particle size indicates that the particle sizes produced by PCA depend primarily on the differential between the solute concentration in organic solvent and the saturated concentration, not necessarily on the properties of a specific solute. Additionally, wider PSDs were observed for higher solute concentrations. Extrapolation of the linear relationship between particle size and relative solute feed concentration suggests that the smallest average diameter of particles produced by PCA is 45 nm, which is in accordance with what has been observed in literature. The smallest average particle sizes reported for PCA processes are on the order of 40–50 nm for several compounds, including lysozyme, rifampicin, and polyvinyl alcohol (PVA). Growth of particle sizes from systems with higher feed solute concentrations may be attributed to an increased concentration of nuclei, which increase collisions rates.

In order to gain a more fundamental understanding of how different operating conditions influence particle properties, several theoretical models have been developed to describe particle formation and growth in the PCA process. Many of the models focus on calculating the rate of mass transfer of antisolvent into the solvent phase because this is believed to be a key factor dictating particle size and morphology. Werling and Debenedetti proposed a model for two-way mass transfer between a droplet of organic solvent and compressed antisolvent that accounts for both subcritical and supercritical conditions (Werling and Debenedetti 1999, 2000). The model assumes that the droplet of organic solvent is stagnant; thus, only mass transfer by diffusion is considered. For subcritical conditions, the solvent droplet initially swells due to the diffusion of antisolvent into the droplet. As the pressure in the system is increased, the lifetime of the solvent droplet decreases because the droplet shrinks as the CO₂-solvent mixture evaporates to induce precipitation. However, as the system tends toward near-critical conditions, the lifetime of the solvent droplet increases drastically because CO₂ diffusivity tends toward zero near the critical point. Longer droplet lifetimes may lead to larger particle sizes because droplet coalescence, and thus particle growth, is more likely. Because distinct droplets do not form under supercritical conditions, a hypothetical interface, based on the density gradient between the solvent-rich and antisolvent-rich regions, was assumed in the model. Modeling results indicated that solvent droplets would swell if the density of the organic solvent was higher than that of the antisolvent. Likewise, the solvent droplets would shrink if the solvent density was lower than that of the antisolvent. The extent of droplet swelling or shrinking is dependent on the system's temperature and pressure, as it affects density and diffusivity differences between solvent-rich and antisolvent-rich domains. In systems near their critical point, solvent droplets undergo greater swelling and experience longer lifetimes, and are more sensitive to operating conditions than systems far from the critical point. Elvassore et al. expanded upon Werling and Debenedetti's model by including the effects of the solute on the diffusivity and density of the SCF into the mass-transfer calculations (Elvassore et al. 2004). The assumption of a stagnant droplet of organic solvent is maintained and the diffusion flux in the solute-solvent-antisolvent system was calculated using Maxwell-Stefan relationships. In this model, slowly diffusing solutes, such as polymers, were found to increase droplet lifetimes by as much as one order of magnitude for high solute concentrations, compared to solutes with faster diffusivities. The extent of a solute's solubility in the solvent-antisolvent mixture also influenced the particles' morphologies, as the evolution of the precipitation front was found to be significantly different for highly soluble and poorly soluble compounds (Elvassore et al. 2004). Perez de Diego et al. proposed a model that accounted for the convective motion of CO₂ (Perez de Diego et al. 2006). Martin et al. has adapted the mass-transfer model developed by Werling and Debenedetti (1999, 2000) to simulate the formation of protein particles by PCA (Martin et al. 2007). More recently, a numerical model utilizing computational fluid dynamics (CFD) calculations (Martin and Cocero 2004) more accurately modeled supercritical systems using a turbulent, gaseous plume to simulate the organic feed stream, instead of the hypothetical spherical droplet used by Werling and Debenedetti (1999, 2000). While each new model includes an additional degree of the PCA process's

complexity to impart further insight, all of the models express similar trends. Droplet lifetimes are shorter for supercritical systems than subcritical systems and shorter growth periods are more likely to lead to smaller particle sizes. When operating in the supercritical condition, the most important mechanism affecting final particle size is primary nucleation, and thus process parameters that facilitate more rapid and higher nucleation rates tend to form smaller particles. Additionally, it is important to design systems away from the critical point of the antisolvent because the near-zero diffusivities at this condition lead to droplets with longer lifetimes, which have a propensity to result in larger particle sizes. However, current models are still not able to universally quantify the dependence of particle size on process parameters for a range of drug–solvent–antisolvent systems. As mentioned previously, multiple interactions within the system (drug–solvent, solvent–CO₂, and drug–solvent/CO₂ solution) significantly affect thermodynamics, hydrodynamic, mass transfer, and mixing and precipitation kinetic behavior, and thus make it difficult to generalize results for a wide range of systems.

12.2.3 Rapid Expansion of Supercritical Solutions (RESS)

In contrast to GAS and PCA processes, the rapid expansion of supercritical solutions (RESS) process utilizes the SCF as a solvent, not an antisolvent. The solute is dissolved directly into the SCF phase in the extraction unit. Then, the system is depressurized across a nozzle into a collection chamber at atmospheric conditions. The sudden depressurization causes evaporation of the SCF, resulting in a significant reduction in solvent power, and thus promotes rapid nucleation and precipitation of the solute. As with the other particle formation techniques discussed previously, additional excipients may be dissolved in the SCF, typically CO₂, to produce composite particles of drug and excipients (Turk 2009). A schematic of the RESS process is shown in Fig. 12.10. Intense atomization of the drug–CO₂ stream is desirable to achieve nanoparticles from the RESS process. Therefore, depressurization of the CO₂ feed stream from the nozzle is designed to be extremely rapid, with typical CO₂ flow rates exiting the nozzle at the speed of sound, creating supersaturation levels on the order of 10⁵–10⁶ within a time frame 10⁻⁶–10⁻⁴ s (Debenedetti et al. 1993). The intense turbulence generated by rapid depressurization of CO₂ distributes the newly generated supersaturation regions almost instantaneously and homogeneously throughout the fluid, which facilitates the production of small particles with narrow PSDs. This rapid dissipation of energy is highly endothermic, and thus the nozzle is generally heated to prevent freezing of CO₂ during atomization, which can cause clogging.

Several process parameters of RESS that have been reported to affect final particle characteristics include the temperature and pressure in the extraction unit, the temperature and pressure of the SCF–drug solution just before atomization, termed as pre-expansion temperature ($T_{\text{pre-exp}}$) and pressure ($P_{\text{pre-exp}}$), respectively, as well as post-expansion temperature (T_{postexp}) and pressure (P_{postexp}). These conditions determine

Fig. 12.10 Schematic of RESS process. Schematic adapted from Martin and Cocero (2008)

the process path along the pressure–temperature (P - T) diagram for the SCF. The P - T diagram for CO_2 is shown in Fig. 12.11. Depending on initial P - T conditions, the expansion pathway may intersect the vapor–liquid saturation line, which may result in significant changes in particle morphology (Martin and Cocero 2008). When the expansion path intersects the solid–liquid saturation line, solid, frozen CO_2 forms during atomization, requiring the nozzle to be heated during operation to prevent clogging. Nozzle design is another parameter that has reportedly influenced final particle properties, as the geometry of the nozzle influences the timescale over which depressurization occurs and, thus, the degree of atomization (Martin and Cocero 2008; Rogers et al. 2001a).

Fig. 12.12 Influence of pre-expansion conditions on particle sizes of benzoic acid and cholesterol prepared by RESS. Reprinted from Turk (2000). Copyright 2000 with permission from Elsevier

To date, however, a definitive relationship between experimental process parameters and particle properties has not been established and, in some cases, experimental results have been inconsistent. For example, for a given $P_{\text{pre-exp}}$, an increase in $T_{\text{pre-exp}}$ from 350 to 425 K resulted in an increase in the size of benzoic acid particles produced by RESS (diameter increased from 0.2 to 1.3 μm), while the particle size of cholesterol remained unchanged ($\sim 0.25 \mu\text{m}$) (Fig. 12.12). Similarly, an increase in $P_{\text{pre-exp}}$ resulted in a decrease in particle size of benzoic acid, while the size of cholesterol particles again remained essentially constant. Numerous studies have been conducted to better understand which process parameters most strongly and consistently influence final particle size. The RESS process commonly produces particles in the 1–5- μm size range, although submicron particles have been produced under specific operating conditions (Gupta 2006). Several RESS studies have been highlighted in Table 12.4. Clearly, process temperatures and pressures and nozzle geometry significantly influence particle size and shape, and, in some cases, morphology (Turk and Bolten 2010). Relatively small adjustments to just one of these operating conditions may significantly impact particle diameter by an order of magnitude, as well as completely alter the particle shape from a sphere to a needle shape, as seen in the cases for salicylic acid and griseofulvin particles produced by RESS (Table 12.4). Based on reports from literature, including those listed in Table 12.4, several trends in processing conditions have been identified to facilitate nanoparticle production (Turk 2009).

- Influence of $T_{\text{pre-exp}}$: An increase in $T_{\text{pre-exp}}$ typically leads to larger particle sizes. For a given operating pressure, even though elevated temperatures may increase

Unless otherwise noted, CO_2 was the solvent

^aFor needle-shaped particles: length/diameter; For spherical particles: diameter; Nonspherical refers to particles that do not possess an aspect ratio typical of needle-shaped particles, but deviate significantly from an aspect ratio of unity (i.e., rectangle with aspect ratio ~ 2). Sizes for nonspherical particles correspond to effective diameters.

^bNR indicates a value that was not reported

^cSolvent was CHF_3

drug solubilities and thus increase supersaturation and nucleation rates (Liu and Nagahama 1996), the higher temperatures also tend to increase turbulence within the mixing chamber, leading to higher instances of particle coagulation (Franklin et al. 2001). The increased rate of particle coagulation appears to outweigh the benefits of enhanced nucleation rates achieved by elevated $T_{\text{pre-exp}}$ conditions.

- Influence of $P_{\text{pre-exp}}$: An increase in $P_{\text{pre-exp}}$ typically leads to smaller particle sizes because a higher pressure results in an increased mass flow rate of CO_2 , which decreases the residence time of the particles in the expansion chamber, reducing the time for particle growth. The reduction in residence time also facilitates the production of more spherical particle shapes, by limiting the time available for additional growth along one axis.
- Influence of nozzle: Nozzles with smaller length-to-diameter (L/D_{noz}) ratios have been found to produce smaller particles, as larger nozzle diameters facilitate increased CO_2 mass flow rates (for a given $T_{\text{pre-exp}}$ and $P_{\text{pre-exp}}$). Additionally, nozzles with smaller L/D_{noz} ratios allow for the pressure drop to occur closer to the free jet (Rogers et al. 2001a; Weber et al. 2002). As the L/D_{noz} ratio is increased, there is an increased propensity for an initial burst of particle nucleation to occur near the nozzle exit. A second round of nucleation occurs upon full expansion of the SCF, resulting in larger particles as well as broader PSDs. Typically, nozzle diameters range from 10 to 50 μm i.d. and length-to-diameter ratios range from 5 to 100 (Young et al. 2000).

It is important to note that these reported trends reflect a considerable portion of the studies in literature, but are not exclusively observed. Deviations from these observed trends, as in the case of cholesterol particles produced by RESS, have been associated with extremely low solute solubilities in SCF and/or solutes that significantly influence the surface tension of the SCF (Turk 2000).

In response to the seemingly conflicting experimental results surrounding the RESS process, several theoretical models have been postulated to gain fundamental knowledge about the RESS process in order to better target optimal process parameters suitable for nanoparticle production. Many of the models focus on the expansion of the SCF in the nozzle to qualify the impact of nozzle design on final particle characteristics. The models show that sonic velocities are achieved at the nozzle outlet and the resultant supersonic jet exiting the nozzle immediately experiences a steep drop in pressure and temperature, causing solute precipitation. Thus, nucleation occurs primarily during free jet expansion. Calculations estimate that nuclei formed in the free jet are as small as 5–10 nm for poorly water-soluble drugs (Gupta 2006; Reverchon and Pallado 1996; Turk et al. 2002). However, intense turbulence within the supersonic free jet often results in significant coagulation between particles before the SCF in the droplets completely evaporates (Franklin et al. 2001; Helfgen et al. 2003). Thus, controlling-expansion conditions may be tuned to facilitate SCF evaporation and minimize droplet coagulation. For example, expansion chamber geometries that minimize the formation of turbulent eddies are desirable to lower the probability of particle coagulation (Helfgen et al. 2003). Additionally, the introduction of an air flow jet into

the expansion chamber resulted in smaller particles by reducing the residence time of the drug particles in the expansion chamber (Helfgen et al. 2003). In addition to the work focused on nozzle design, other models have examined particle formation and growth within an SCF. The theories used to describe particle growth in gaseous and liquid phases were also found to be applicable, with minor adjustments, for supercritical precipitation processes. Debenedetti (1990) and Turk (2000) calculated nucleation rates achieved in the RESS process using a modified definition for supersaturation, S , which was adjusted to account for the highly nonideal behavior of SCF by including fugacity, f , as a thermodynamic correction factor.

$$S = \frac{C_{\text{drug}}}{C_{\text{eq}}} \frac{f(T, P, C_{\text{drug}})}{f(T, P, C_{\text{eq}})}. \quad (12.7)$$

Helfgen et al. applied the modified supersaturation term in conjunction with the general dynamic equation for aerosols, commonly used to describe particle growth in aerosols (Pratsinis 1988), to predict particle nucleation and growth rates in RESS. Results from the model indicated that the majority of particle precipitation and growth took place in the free jet and that turbulent coagulation in the free jet is the primary mechanism of particle growth (Franklin et al. 2001; Helfgen et al. 2003). Relatively good agreement between the model and experimental results were demonstrated for the production of benzoic acid, griseofulvin, and β -sitosterol by RESS (Helfgen et al. 2003). While trends relating particle size to experimental parameters such as nozzle design and pre- and postexpansion conditions identified by various models have been in accordance with experimental observations, quantitative determination of nucleation and growth rates for a wide range of drug systems remains challenging because reasonable values for some model parameters cannot be determined experimentally and must be assumed.

RESS does not require organic solvents and may be operated at moderate temperatures (typically below 80°C). However, the primary drawback of RESS is low process yields. Most organic solids possess low solubility in scCO_2 due to the low polarizability of CO_2 . Therefore, large amounts of SCF are required to produce relevant batch sizes. For example, the solubility of griseofulvin in scCO_2 is only 18 ppm. Therefore, the production of 18 moles (~6 kg) of griseofulvin by RESS would require one million moles (~44,000 kg) of CO_2 . Recovery of the resultant particles is also challenging, as efficient filtration is required to remove such large volumes of solvent (Gupta 2006). To increase drug loading, extraction temperatures and pressures may be increased. The addition of cosolvents, such as methanol, acetone, and ethanol, to scCO_2 has also been used to increase drug solubility. However, this tactic is not always recommended as it may lead to solubilization of the particles in the cosolvent. Additional methods to increase process yields and reduce particle coagulation for RESS-based techniques are discussed in the next section.

Fig. 12.13 Schematic of RESAS process, inset is a photograph of the spray of the CO₂ solution stream expanding through a tapered elliptical nozzle with a flow rate of 2.5 mL/min at 345 bar. Adapted from Young et al. (2000, 2003)

12.2.4 Modified RESS Processes

RESS into aqueous solutions: Rapid Expansion from Supercritical to Aqueous Solution (RESAS) and Rapid Expansion Of a Supercritical Solution into a Liquid Solvent (RESOLV)

To address the significant particle growth that occurs in the RESS process due to particle collisions during free jet expansion, the process was modified by directing the atomized drug–SCF solution into an aqueous solution to provide a barrier against particle growth. This modified RESS process was coined RESAS, also known as RESOLV. In RESAS/RESOLV, the supercritical solution is atomized through a nozzle directly into an aqueous solution containing a stabilizer, typically a surfactant. A schematic for the RESAS/RESOLV process is shown in Fig. 12.13. The nozzle is placed below the surface of the aqueous solution to promote intimate contact between the newly formed nuclei exiting the nozzle and the stabilizers dissolved in the aqueous media. Because the turbulent expansion of CO₂ in a surfactant solution produces considerable amounts of foam, nitrogen is streamed above the aqueous solution to disrupt the foam and facilitate drainage back into the bulk liquid phase (Young et al. 2000).

By atomizing the SCF stream into a surfactant solution, particle growth in the free jet may be arrested by the rapid adsorption of surfactant molecules to the newly

formed particle surfaces. Young et al. demonstrated the ability of the RESAS process to produce ~500-nm particles of the poorly water-soluble drug, cyclosporin A (CsA), using Tween 80 as a stabilizer (Young et al. 2000). In contrast, CsA particles produced by RESS, where the scCO₂ solution was sprayed into air instead of a Tween 80 solution, were 3–50 μm in diameter. As a control, the scCO₂ solution was also sprayed into water containing no surfactant to validate the role of Tween 80 in impeding particle coagulation and growth. Resultant particle sizes ranged between 0.23 and 4.10 μm. Therefore, inhibited CsA particle growth in the RESAS process is attributed to the rapid diffusion of Tween 80 to particle surfaces and its ability to provide steric stabilization to the particles.

The successful production of drug nanoparticles by RESAS/RESOLV has also been demonstrated for ibuprofen (40–80 nm in diameter when stabilized by Tween 80 (Turk 2009) or polyvinylpyrrolidone (PVP_{40K}) (Pathak et al. 2004, 2006), naproxen (64 nm when stabilized by PVP_{40K}) (Turk 2009), and paclitaxel (200–530 nm when stabilized by PVP_{40K} or PVP_{360K}) (Pathak et al. 2007). However, for these cases, the drug/polymer ratio was typically <<1, ~0.08–0.2. To better understand how to efficiently increase the drug potency of RESAS particles while still maintaining submicron particle sizes, the critical processing parameters for the RESAS process were investigated by Young et al. (2000, 2003, 2004). Experimental parameters such as surfactant selection, temperature of the aqueous reservoir, and final drug concentration, in addition to the operating parameters known to influence particle properties in RESS, were varied to manipulate the efficiency of surfactant molecules to stabilize nanoparticles (Young et al. 2000). Nonionic surfactants, Pluronic F127 (also known as poloxamer 407) and Myrj 52, in addition to Tween 80, were explored in efforts to stabilize CsA particles. CsA particles stabilized by Pluronic F127 and Myrj 52 were about twice as large (>840 nm in diameter) as those stabilized by Tween 80 (500 nm in diameter) when produced at similar operating conditions, emphasizing the importance of selecting stabilizers with sufficient affinity for the drug particle surface and adequate chain length to provide steric repulsion. In contrast, a phospholipid-based surfactant produced CsA particles with a mean diameter of 220 nm, about half the size of the Tween 80-stabilized particles produced by RESAS at similar operating conditions. However, higher amounts of phospholipid were necessary to stabilize the smaller CsA particles compared to Tween, only achieving a drug/surfactant ratio of 0.1 compared to 0.65 for Tween-stabilized particles. In the case of phospholipids, the bulk of the surfactant arranges to form vesicles. The aggregation number of surfactant molecules is much larger for vesicles than for micelle-forming surfactants such as Tween, which explains the lower drug/surfactant ratios observed for phospholipid stabilizers. The temperature of the aqueous reservoir is also a key parameter for the RESAS process, as it influences the surfactant assembly and thus the rate at which the surfactant is able to reach the particles' surface. Phospholipid stabilizers are especially sensitive to temperature because vesicles tend to become rigid at temperatures below 25°C. Hence, phospholipids are more effective stabilizers when heated to higher temperatures and facilitate the stabilization of smaller particles. Under optimized conditions ($T_{\text{aqueous bath}} = 80^{\circ}\text{C}$, CsA concentration in CO₂ = 54 mg/mL, CO₂ flow rate through nozzle = 2.5 mL/min,

and pressure drop across nozzle = 345 bar), a phospholipid surfactant mixture stabilized ~500-nm CsA particles (31% w/w drug) at drug suspension concentrations up to 5.4% w/w (Young et al. 2004). The increase in drug suspension concentration resulted in slightly increased particle sizes, compared to the 220-nm CsA particles when suspension concentrations were held to 1.3% w/w (Young et al. 2004).

The RESAS process was shown to successfully produce smaller particles of water-insoluble materials than was achieved by RESS due to particle stabilization within an aqueous surfactant solution. In the case of mild particle aggregation after RESAS precipitation, a high-pressure homogenization step has been added to the end of the RESAS process to promote more uniform PSDs and to break up any aggregates that may have formed. This process train has been patented by RTP Pharmaceuticals Inc., and was later licensed by Baxter Healthcare Corporation for incorporation into their NANOEDGE technology (Hu et al. 2004; Keck and Mueller 2006). The primary limitation of RESAS, as in the RESS process, is that the solute must possess moderate solubility in an SCF.

12.2.4.1 Rapid Expansion of Supercritical Solutions with Solid Cosolvents (RESS-SC)

In the RESS-SC process, a cosolvent that solidifies upon atomization from the nozzle is used to enhance the solubility of solutes in $scCO_2$, as well as provide a barrier for coagulation in the free jet during $scCO_2$ expansion (Thakur and Gupta 2005). In contrast to RESS, where the nuclei tend to coagulate during free jet expansion, the excess amounts of solid cosolvent added during the RESS-SC process surrounds the nuclei to create a physical barrier to reduce coagulation. The cosolvent may be removed later by lyophilization. A schematic representing the RESS-SC technique, in contrast to RESS, is shown in Fig. 12.14.

In addition to the typical operating parameters that are important in RESS, clearly, the selection of the solid cosolvent is a key parameter in the RESS-SC process. The solid cosolvent must be nonreactive with the drug and CO_2 , possess good solubility in $scCO_2$, be in the solid state at the nozzle exit, have a reasonably high vapor pressure to facilitate removal by sublimation, and, preferably, inexpensive since excess amounts are needed to maintain submicron particle sizes. Thus far, menthol has been the most prevalently used solid cosolvent for RESS-SC applications. Menthol is a natural product extracted from mint-flavored plants, possesses a melting point of 42°C, and satisfies all the criteria listed above. Menthol enhanced the solubility of the poorly water-soluble drug griseofulvin 28-fold in $scCO_2$, enabling the production of 50–250-nm particles by RESS-SC, which is an order of magnitude smaller than those produced by RESS, at a 28-fold increase in payload. Aminobenzoic acid (80-nm mean diameter) and phenytoin (120-nm mean diameter) particles have also been produced using the RESS-SC process (Thakur and Gupta 2005, 2006a, b). The RESS-SC technique broadens the applicability of the RESS process to more drugs, as well as facilitates the production of higher payloads

Fig. 12.14 (a) Schematic of the RESS process and (b) RESS-SC process. Circles represent drug particles and stars represent solid-cosolvent particles. Reprinted with permission from Thakur et al. (Thakur and Gupta 2005). Copyright (2005) American Chemical Society

compared to RESS. However, not all drugs exhibit increased solubility with the presence of menthol, and thus RESS-SC is not a universal solution for all drug systems.

12.2.4.2 Particles from Gas Saturated Solutions (PGSS) Process

The PGSS process flow is similar to RESS, but differs in the case that CO_2 does not act as a solvent. In PGSS, the CO_2 is dissolved in a melted solid and the mixture is depressurized through a nozzle. Expansion of the dissolved CO_2 results in intense atomization and cooling of the molten solid, and thus precipitation of particles. This process is suitable for materials with a large solubility in CO_2 , such as PEGs and oils (Martin et al. 2010; Perrut et al. 2005). Benefits of this process are that it consumes less CO_2 than the previously discussed SCF technologies, may be operated under moderate pressures (10–15 MPa), and solubility of the drug in the CO_2 is not necessary to achieve high process yields, as the drug can be dispersed in the melted solid (Martin et al. 2010; Perrut et al. 2005). Therefore, this precipitation process is optimal for polymer encapsulation and is capable of particle micronization, typically yielding micron-sized particles, larger than achieved by RESS (~3–60 μm for theophylline and PEG 6000 (Martin et al. 2010; Rodrigues et al. 2004). Theoretical models that describe the PGSS process, which were built upon existing RESS models, suggest that the larger particles produced by PGSS compared to RESS are due to significant coagulation in the free jet region (Martin and Cocero 2008; Li et al. 2005).

12.2.5 Comparison of Precipitation Processes Utilizing Supercritical Fluids

SCF precipitation technologies have demonstrated the ability to produce submicron particles of poorly water-soluble drugs. However, the creation of submicron particles is not considered typical for any of the processes, as 1–5- μm particles are commonly produced. The experimental research in this area has been predominantly descriptive, rather than predictive, with the conclusions heavily dependent upon the materials and conditions of that specific study. The inability to develop generalized models that accurately predict final particle sizes with respect to different operating parameters over a wide range of drug systems is due to the simultaneous influence of the operating parameters on multiple particle formation and growth factors, such as thermodynamics, fluid mechanics, mass transfer, and mixing and precipitation kinetic behavior. Despite case-specific results, general attributes of the different processes may be identified to provide general guidelines as to the capabilities of each process. Comparisons between the different SCF micronization options are shown in Table 12.5.

Generally, GAS processes produce larger particles than PCA processes, primarily due to the higher mass-transfer rates achieved in PCA. Characteristic mass-transfer times (τ_{mt}) for GAS and PCA processes have been calculated based on models developed by Lin et al. and Werling and Debenedetti (Fusaro et al. 2005; Werling and Debenedetti 1999, 2000; Lin et al. 2003).

$$\tau_{\text{mt}}^{\text{GAS}} = M_0 / M_{\text{CO}_2}, \quad (12.8)$$

$$\tau_{\text{mt}}^{\text{PCA}} = t_{\text{max}} V_0 / (V_{\text{max}} - V_0). \quad (12.9)$$

where M_0 is the initial amount of solvent, M_{CO_2} is the CO_2 addition rate, t_{max} is the time for the solvent droplet in the PCA process to swell to its maximum diameter, V_0 is the original volume of the solvent droplet prior to swelling, and V_{max} corresponds to the volume of the solvent droplet at its maximum diameter. In the GAS process, the mass-transfer rate is a function of the CO_2 addition rate. In PCA, the mass-transfer rate is correlated to the change in volume of the solvent droplet due to the mass transfer of CO_2 into the droplet. Figure 12.15 illustrates the effect of characteristic mass-transfer times on particle size, based on Lin's model. The estimated range of mass-transfer times for PCA is about 2 orders of magnitude smaller than that for the GAS process, further validating the theory that the primary difference between these two processes is the mass-transfer rates that can be achieved. These mass-transfer rates correlate directly with rates of generation of supersaturation, and thus give an indication of characteristic nucleation times. These estimates were confirmed experimentally by the precipitation of the poorly water-soluble drug paracetamol using both GAS and PCA. Mean particle sizes ranging from 90 to 250 μm

Table 12.5 Comparison of micronization techniques using compressed fluids

| Process | Temperature (°C) | Organic solvent required | Compressed fluid as solvent | Compressed fluid as antisolvent | Yields poorly water-soluble nanoparticles |
|-------------------|------------------|--------------------------|-----------------------------|---------------------------------|---|
| GAS | 25–80 | Yes | No | Yes | Yes |
| PCA/SAS/ASES/SEDS | 25–80 | Yes | No | Yes | Yes |
| RESS | ≤100 | No | Yes | No | Yes |
| RESAS | 25–80 | No | Yes | No | Yes |
| PGSS | ~25–40 | No | No | No | No |

were produced by GAS precipitation, in comparison to 1.3–2.5 µm for PCA. Corresponding mass-transfer times were 20–900 s and 0.04–0.12 s for GAS and PCA, respectively, in the range predicted in Fig. 12.15.

In contrast to GAS and PCA, precipitation by RESS results from a sudden change in pressure, which causes a decrease in solvent power, and thus prompts nucleation and precipitation of particles. Depressurization of CO₂ during RESS has been reported to occur at the speed of sound, corresponding to timescales on the order of 10⁻⁶–10⁻⁴ s (Debenedetti et al. 1993). Because the timescale over which depressurization occurs may be correlated to the timescale during which nucleation occurs,

one may expect RESS to be capable of producing smaller nanoparticles, compared to PCA and GAS. However, collisions in the free jet lead to particle growth and similar particle sizes, unless a solvent containing a stabilizer is utilized as in RESAS and RESOLV or RESS-SC. Additionally, RESS does not utilize organic solvents and therefore minimizes environmental and toxicity concerns regarding residual solvent levels. PGSS requires neither organic solvents nor the solute to possess high solubility in CO_2 , thus facilitating large process yields. The primary drawback to PGSS is that significant coagulation between primary particles occurs during processing, resulting in typical particle sizes greater than several microns.

12.2.6 *Evaporative Precipitation into Aqueous Solution (EPAS)*

To address the solubility restrictions that have limited the applicability of SCF precipitation technologies for nanoparticle production, the evaporative precipitation into aqueous solution (EPAS) process was developed based upon similar operating principles as RESAS. In EPAS, the drug is dissolved in an organic solvent and then atomized into a heated aqueous solution. Stabilizers may be incorporated into the organic or aqueous phase, or both. A schematic representing the EPAS process is shown in Fig. 12.16. The elevated temperature of the aqueous solution facilitates rapid evaporation of the organic solvent, which induces supersaturation and subsequent nucleation of the drug. The large interfacial area produced by the nucleating

surfaces provides a strong driving force for the adsorption of the stabilizers to the newly formed particles. Passivation of the particle surface by stabilizers hinders particle growth via condensation and coagulation. The resultant particles may be harvested by filtration, lyophilization, or spray drying of the drug dispersion (Sarkari et al. 2002). Because organic compounds generally possess significantly higher solubilities in organic solvents as compared to SCFs, particularly CO₂, the EPAS process is more amenable to a wider variety of APIs and can achieve higher process yields, compared to RESAS.

The key operating parameters that impact particle size and morphology in the EPAS process are similar to those mentioned for RESAS, as EPAS parallels RESAS in many aspects. However, the evaporation of CO₂ droplets is more rapid than for an organic solvent. Droplet formation is well defined in RESAS because CO₂ is only slightly miscible with water. In EPAS, dichloromethane (DCM) has been chosen as the organic solvent because of its similar low miscibility with water in addition to its ability to solubilize a variety of organic compounds. Minimizing the miscibility of the organic solvent with the aqueous solution reduces particle growth via Ostwald ripening and limits the tendency of the organic solvent to interfere with the capabilities of the surfactant to coat the particles and provide steric stabilization. For CsA particles stabilized with Pluronic F127, smaller particles were produced when DCM was chosen as the organic solvent versus diethyl ether (mean particle diameter of 423 nm versus 1218 nm using DCM and diethyl ether, respectively) (Chen et al. 2002). Both solvents possess similar volatilities and heats of vaporization (Carl 1999). However, at the aqueous reservoir temperature of 75°C, the solubility of DCM in water is 4 mg/mL, compared to 12 mg/mL for diethyl ether.

Due to the similar particle formation mechanisms of EPAS and RESAS, key EPAS operating parameters also include nozzle design, process temperature, stabilizer selection and concentration, and final suspension concentration in the aqueous phase. The nozzles used in EPAS processes are similar to those for RESAS, targeting intense atomization of the organic solution into the aqueous bath to facilitate rapid nucleation, as well as rapid diffusion of the stabilizers to the particle surfaces. In terms of process temperature, the organic solution is often heated to improve the solute solubility in the organic solution, in addition to promoting more rapid evaporation of the solvent and, thus, supersaturation and nucleation. For similar reasons, the aqueous reservoir is also typically heated, to accelerate evaporation, and, thus, nucleation rates. Higher temperatures in the aqueous reservoir also promote the diffusion of the stabilizers to the particle surface. Chen et al. (2002) showed that the size of polyvinylpyrrolidone (PVP)-stabilized CsA particles decreased from 1,354 to 803 nm when the temperature of the aqueous solution was increased from 55 to 85°C. However, the opposite trend was observed for CsA particles stabilized with Tween 80 where, under the same operating conditions, mean particle size increased from 308 to 774 nm for the same temperature increase. In the case of ethoxylated surfactants, such as Tween 80, high temperatures weaken the hydrogen bonding between the ethylene oxide groups and, thus, hinder steric stabilization (Blankschtein et al. 1986). High temperatures also have an adverse effect on some triblock copolymers, such as Pluronic F127, in which the solution viscosity increases for elevated

temperatures, resulting in longer diffusion times (Sinswat et al. 2005). Therefore, the effect of temperature on stabilizer performance should be considered during stabilizer selection. Another parameter that must be addressed, due to its influence on supersaturation levels, is the drug concentration in the feed solution. Unlike RESAS, in which the drug concentration is limited by low solubility in CO₂, feed concentration may be varied in EPAS due to the larger solubilities of drugs in organic solvents. When the feed CsA concentration was increased from 1 to 5% w/v, the average size of CsA particles decreased by at least 40%, down to submicron particles, when stabilized by several different surfactants (Chen et al. 2002). The higher drug concentrations in the feed generated higher degrees of supersaturation during solvent evaporation, leading to smaller particles.

Typical particle sizes generated by EPAS, as determined by light scattering, are in the range of 1–10 µm. However, analysis of the particles by microscopy and Brunauer–Emmett–Teller (BET) surface-area measurements suggests that the micron-sized entities are actually aggregates of smaller, submicron particles (Vaughn et al. 2005; Sinswat et al. 2005). As the solvent evaporates and nucleation occurs, the nuclei become more concentrated as the organic droplet shrinks, which increases the probability of coagulation. Thus, effective stabilization after nucleation is necessary to maintain small particle sizes. The selected stabilizer should diffuse rapidly in the appropriate solvent, have sufficient chain length to provide steric stabilization, and have a high affinity for adsorption of the drug surface. In general, larger-molecular-weight (MW) stabilizers take longer to diffuse to particle surfaces, compromising final particle size. On the other hand, the greater radius of gyration provides better steric stabilization. Therefore, the need for rapid diffusion to the particle surface must be balanced with the need for a surfactant with sufficient MW to provide effective steric stabilization. Several studies have compared the steric capabilities of various surfactants. For example, CsA particles prepared by EPAS using Tween 80 or Myrj 52 were ~500–600 nm in diameter, compared to ~1,100 nm when stabilized using higher MW PVP 40 T under the same operating conditions. However, PVP 40 T was found to be a better stabilizer for danazol particles produced by EPAS, compared to lower MW surfactants such as Pluronic F127, sodium lauryl sulfate (SLS), and sodium deoxycholic acid (DCA). PVP-stabilized danazol particles were 10–17 µm in diameter, compared to 22–30-µm particles when stabilized by the lower MW surfactants (Chen et al. 2004a). It is interesting to note the large disparity between the sizes of the CsA and danazol particles stabilized with PVP 40 T, under similar operating conditions. PVP-stabilized CsA particles produced by EPAS ranged between 600 and 1,100 nm in diameter for final dispersion concentrations between 1 and 5% w/v, whereas PVP-stabilized danazol particles were 10–17 µm when prepared at a 2% w/v aqueous dispersion (Chen et al. 2002, 2004a). This difference in size highlights the fact that stabilizer selection is highly dependent upon the affinity of a stabilizer to adsorb on a particular drug surface, in addition to growth rates for particular drugs.

In EPAS, another factor to consider when selecting the appropriate surfactant is whether to incorporate the stabilizer into the organic phase, in addition to the aqueous phase. The addition of effective amounts of stabilizers to the SCF phase was not

plausible in RESAS due to the low solubility of many stabilizers, especially high-MW polymers, in SCFs. The addition of a stabilizer to the organic phase in EPAS has enabled the production of smaller particles, compared to systems where the stabilizer is only present in the aqueous phase, because less time is required for the surfactant to diffuse to the particle surface, as it does not need to cross the aqueous/solvent boundary. The average diameter of carbamazepine (CBZ) particles prepared by EPAS stabilized using Pluronic F127 was ~20% lower when the Pluronic was integrated into the organic phase versus the aqueous phase (mean diameter of 13 and 16 μm , respectively) (Sarkari et al. 2002). When stabilizers were added to both the organic and the aqueous phases, even smaller particles were created, about 40% lower than when Pluronic was added only to the aqueous phase. The ability to reduce particle sizes by including stabilizers in both the organic and aqueous phases during EPAS precipitation was also demonstrated for danazol and itraconazole (Itz) particles, where particle-size reductions up to one order of magnitude were achieved, down to submicron levels, depending on the selected combination of stabilizers (Vaughn et al. 2005; Sinswat et al. 2005).

Interestingly, high-potency particles, greater than 50% w/w drug, may still be produced by EPAS despite increasing the concentration of stabilizers in both the organic and aqueous phases. As mentioned previously, particle growth is impeded by the adsorption of stabilizers to the particle surface. Because the hydrophilic portions of the surfactant favor the drug–water interface, relative to the hydrophobic particle interior, the surfactant selectively orients itself at the particle surface (Matteucci et al. 2007). Upon passivation of the particle surface, the loading of surfactant is limited by the equilibrium adsorption. Therefore, the most effective strategy for stabilizing particles produced by EPAS is to accelerate surfactant adsorption to the nucleating surfaces through surfactant selection and placement and to use excess amounts of surfactant. Unadsorbed surfactant may be removed by centrifugation after precipitation (Vaughn et al. 2005; Sinswat et al. 2005). EPAS production of Itz yielded particles with a BET surface area of 6.31 m^2/g (~731 nm in diameter, assuming a spherical geometry) and 93.8% w/w potency when the stabilizer, Pluronic F127, was added to both the organic and aqueous phases (Sinswat et al. 2005; Chen et al. 2004b). When Itz was stabilized using PVP-K15 by EPAS, particles as small as 500 nm in diameter were achieved for a drug-to-excipient ratio of 0.79 (Chen et al. 2004b). It should be noted, however, that slightly larger particle sizes are generally observed as the drug/surfactant ratio (i.e., drug potency) is increased (Chen et al. 2002, 2004b, 2006). For the precipitation of CsA particles with Tween 80 as the stabilizer, the mean particle size increased from 338 nm to 523 nm to 921 nm when the drug-to-excipient ratio was increased from 0.33 to 0.72 to 2.50, respectively (Chen et al. 2002).

Contact-angle measurements verified that the hydrophilic stabilizer sufficiently coated the surface of the particles, as expected, given the colloidal stability. For these measurements, the drug dispersions produced by EPAS were centrifuged to remove unadsorbed surfactant, dried, and the resultant powder was compacted into a tablet. The contact angle observed for a droplet of water on the tablet surface was then measured. The contact angle for Itz tablets prepared from EPAS powder

was ~32% smaller than that for a tablet prepared from a physical mixture of the identical composition, validating the claim that the EPAS process tends to orient the stabilizers to the particle surface (Sinswat et al. 2005). Additional studies have verified these results, where high-potency particles of carbamazepine and danazol produced by EPAS, composed of at least 50% w/w drug, possess smaller contact angles than identical formulations prepared as a physical mixture (Vaughn et al. 2005; Sarkari et al. 2002). The lower contact angles of the EPAS particles also indicate enhanced wettability over the physical mixtures, which is especially important to achieve favorable dissolution rates for poorly water-soluble drugs. Because the EPAS process preferentially concentrates the surfactant at the particle surface, where steric and wetting capabilities are maximized, only small amounts of surfactant are required to stabilize particles with high drug potency and to improve wettability for enhanced dissolution.

Due to the ability of EPAS to produce particles with good surfactant coverage, high drug suspension concentrations can be obtained, typically between 15 and 50 mg/mL, which is highly attractive for parenteral applications (Vaughn et al. 2005; Sarkari et al. 2002; Sinswat et al. 2005). However, for higher suspension concentrations, larger particle sizes, as well as broader PSDs, are observed. When higher suspension concentrations are desired, it is often beneficial to increase the surfactant concentration in the system, to ensure sufficient coverage of the drug particles. An additional benefit of the well-stabilized EPAS particles is that after drying the drug dispersion, the powders have been shown to redisperse to sizes similar to those present in the original dispersion, indicating good stabilizer coverage of the particles (Chen et al. 2004a). Moreover, the EPAS process was shown to produce both crystalline and amorphous particles, depending on the stabilizers chosen. Rapid stabilization of particles, before molecules are able to rearrange into the crystalline structure, leads to higher amorphous content in the particle. Table 12.6 summarizes some particle properties achieved through precipitation by EPAS.

12.3 Antisolvent Precipitation Using Organic Solvents (AP)

The AP process, in which organic solvents make up the solvent phase, is one of the most common bottom-up approaches for particle formation. AP processes are relatively simple, cost effective, and may be operated continuously, facilitating scale-up. The scalability of AP processes has been demonstrated by Novartis for the production of hydrosols and by Soliqs/Abbott for Nanomorph products (Keck and Mueller 2006). Similar to EPAS, larger process yields are generally obtained from AP operations, as compared to SCF-based techniques, because organic compounds possess higher solubilities in organic solvents than in SCFs. Additionally, many of the same particle formation mechanisms discussed for EPAS apply to AP technologies. In AP, the poorly water-soluble drug is first dissolved in an organic solvent and then the drug solution is mixed with an antisolvent, often water. As the two phases mix, the drug solubility decreases, resulting in supersaturation of the drug,

Table 12.6 Drug particles produced by EPAS

| Drug | Stabilizer | API/stabilizer | Mean particle diameter (μm) | Dispersion loading (mg/mL) | Amorphous |
|---|-----------------------------------|---|--|----------------------------|------------------------------------|
| Iz (Chen et al. 2004b; Sinswat et al. 2005) | PVP-K15 | 0.9–0.7 | ~0.51 (BET:9 m ² /g) | 10 | No |
| | Pluronic F127 | | | | |
| | Combination | | | | |
| CsA (Chen et al. 2002) | Tween80 | 9.5–15 | ~730–1,500 (BET:3.1–6.3 m ² /g) | 15 | No |
| | PVP-K15 | | | | |
| | Pluronic F127 | | | | |
| | Combination | | | | |
| | L- α -phosphatidyl-choline | 0.14–0.35 | 0.25–0.47 | 14–35 | Yes |
| CBZ (Sarkari et al. 2002) | Brij | 0.3–0.5 | 0.033–1.04 | 5–50 | Yes |
| | Myrij | | | | |
| | Tween | | | | |
| | PEGs | 0.3–0.5 | 0.077–1.39 | 5–50 | Yes |
| | PVPs | | | | |
| | Dooxycholic acid | 0.45–0.83 | 12–19 | 9–40 | Yes |
| | PVP-K15 | | | | |
| | Sodium dodecyl sulfate | | | | |
| | Pluronic F127 | | | | |
| | PVPs | 0.5–4 | 12–30 | 5 | No, but ~20% reduced crystallinity |
| Danazol (Chen et al. 2004a; Vaughn et al. 2005) | Sodium dodecyl sulfate | | | | |
| | Dooxycholic acid | | | | |
| | Pluronic F127 | | | | |
| | Combination | | | | |
| PVP-K15 | 1 | 0.62 (BET:7.41 m ² /g)/~0.15–0.5 μm drug domains in 7–10 μm aggregates | Not reported | Yes | |

which drives nucleation. Unlike EPAS, an organic solvent that is miscible with the antisolvent is selected to facilitate mixing between the two phases. Diffusion of the organic solvent into the aqueous phase tends to spread the nuclei apart, reducing coagulation rates compared to EPAS, in which droplet shrinkage during solvent evaporation tends to promote coagulation of nuclei. Stabilizers may be added to the solvent or antisolvent phases to further mitigate particle growth by condensation and coagulation. The hydrophilic segments of the stabilizer preferentially extend toward the aqueous environment and, thus, the stabilizer adsorbs at the drug–water interface and not within the interior of the particle. Passivation of the particle surface by the stabilizers hinders particle growth. The selective orientation of the stabilizer at the particle surface facilitates the production of stable, high-potency drug particles with a minimum stabilizer to drug ratio. An illustration of the driving mechanism for the AP process is shown in Fig. 12.17.

In the previously discussed precipitation-based particle formation techniques, micron-sized particles are more commonly produced than submicron particles. In AP, process and formulation parameters can often be manipulated to yield submicron particles. A contributing factor to the higher propensity for AP to form nanoparticles is the miscibility between the solvent and antisolvent, which facilitates both rapid supersaturation as well as efficient adsorption of stabilizers to nucleating drug particles. Additionally, atomization of a partially miscible drug solution into the aqueous phase is not necessary to achieve small particles because the solvent and antisolvent are fully miscible. Therefore, a critical determinant of final particle size is the efficiency of mixing between the antisolvent and solvent phases. The impact of mixing on particle formation may be described by the Damkohler number (Da), defined as the ratio of mixing time (τ_{mix}) to precipitation time (τ_{prec}).

$$Da = \tau_{\text{mix}} / \tau_{\text{prec}} \quad (12.10)$$

Fig. 12.18 Diameter of β -carotene particles produced by AP, as a function of the stream velocity of the organic drug solution into an aqueous antisolvent. An increase in stream velocity results in a decrease in particle size until the break point is reached. Adapted and reprinted with permission from Johnson et al. (2006). Copyright (2006) American Chemical Society

τ_{prec} is a function of condensation time, τ_{cond} , and coagulation time, τ_{coag} (refer to Fig. 12.1). Poor mixing conditions (i.e., large τ_{mix} , resulting in a large Da) lead to low, and often nonuniformly distributed, levels of supersaturation, which subsequently result in slower nucleation rates, relative to particle growth rates. These poor mixing conditions tend to produce large polydisperse particles.

Favorable operating conditions promote rapid mixing, and thus facilitate the production of smaller particles, as characterized by Da values near unity. A reduction in Da may be accomplished by generating greater supersaturation via more rapid nucleation (to reduce τ_{mix}) and/or by extending the time for condensation and coagulation via the addition of stabilizers (to increase τ_{prec}). When Da is equal to unity, the particle formation process is insensitive to further reductions in mixing time. Figure 12.18 illustrates this concept, where the size of β -carotene particles was found to decrease with increased jet velocity, which influences mixing intensity, until a threshold value was reached (Johnson et al. 2006). Above this threshold, the particle size remained constant with further increases in jet velocity. Therefore, when $Da > 1$, the particle formation process is "transport controlled," signifying that mixing times may be optimized to achieve smaller particles. However, if conditions correspond to a $Da \leq 1$, the process conditions have already been optimized to minimize particle size and only a reduction in drug concentration or a change in solvent or stabilizer selection may offer further improvements for particle size reduction.

The limits of AP processing parameters were thoroughly investigated by Matteucci et al. to gain a solid understanding of the impact of process parameters on

the mechanisms driving particle formation and stabilization, primarily for cases where high drug loadings are desired. In the study, Itz, the model poorly water-soluble drug, was stabilized using the amphiphilic polymer Pluronic F127 (P127). Process parameters including stabilizer concentration, the phase in which the stabilizer is added, process temperature, and mixing intensity between the organic and aqueous phases were examined. As in EPAS, higher concentrations of stabilizers resulted in smaller particles when prepared by AP, as expected. Additionally, for a given amount of stabilizer, smaller particles were obtained when the stabilizer was added to the organic versus the aqueous phase. Therefore, for P127-stabilized-Itz particles of similar sizes, a 50% w/w drug loading can be achieved when P127 is added to the organic phase, compared to only a 25% w/w Itz loading when P127 is incorporated in the aqueous phase. Another important process parameter for both EPAS and AP is the final suspension concentration. As in EPAS, increased suspension concentrations, which were achieved by increasing feed drug concentrations, generally led to larger particle sizes during AP unless stabilizer levels were also increased accordingly. However, upon reaching a threshold stabilizer level, Itz drug loadings up to 86% w/w were produced at minimal cost to particle size. In fact, the PSD did not change significantly when the solid loading in the final suspension was varied between 1.8 and 8.9 mg/mL. Matteucci et al. calculated nucleation and growth rates using a population balance model in conjunction with the mixed-suspension, mixed-product-removal crystallization (MSMPR) model to characterize nucleation and growth kinetics (Jarmer et al. 2004), in order to justify the differences in PSD for different experimental parameters.

The temperature of the aqueous bath, into which the organic drug solution is introduced, was also shown to heavily influence final particle size. Matteucci et al. reported that the average particle size of Itz particles stabilized with P127 increased only 15% when the temperature was raised from 3 to 10°C. However, particle sizes increased by a factor of 40 when the temperature of the aqueous reservoir was set near room temperature, at 20°C. The operating temperature influences several aspects of the particle formation process. While higher temperatures generally increase diffusion rates to allow stabilizers to quickly reach growing particle surfaces, they also tend to cause an increase in drug solubility in the solvent/water mixture, which reduces supersaturation and nucleation rates and increases the propensity for Ostwald ripening, all of which leads to larger particle sizes. Additionally, elevated temperatures tend to desolvate amphiphilic molecules due to weakened hydrogen bonding with water, which may reduce steric stabilization. Unlike EPAS, where higher temperatures are needed to facilitate solvent evaporation and, thus, subsequent supersaturation, smaller particle sizes are expected when the aqueous reservoir is maintained at lower temperatures during antisolvent precipitation. For Itz particles stabilized with P127, Matteucci et al. recommended operating at a precipitation temperature of 3°C (Matteucci et al. 2006).

To examine the role of mixing energies, characterized by Re , on final particle size, the intensity by which the organic solution was introduced to the aqueous phase was adjusted by varying nozzle diameters and jet velocities. Not surprisingly, smaller nozzle diameters and higher jet velocities, which create higher Re conditions, tended

^a D_{50} and D_{90} refer to the diameter at which the cumulative sample volume was under 50% and 90%, respectively

*Crimped nozzle refers to a 0.03" i.d. stainless-steel tubing that was crimped and then filed at the cut end until a stable atomized flow was achieved, as described in Young et al. (2000)

to yield smaller particle sizes. However, Matteucci et al. found that particles with sizes similar to those produced under high Re conditions could still be produced under low or moderate mixing energies by adjusting other experimental parameters to push the Da back toward unity, such as increasing the flow rate of the organic solution (decreases τ_{mix}) and/or increasing the stabilizer concentration in the aqueous bath (increases τ_{prec}). Therefore, compensation for a nonoptimal mixing intensity by tuning another process parameter toward a more-optimal setting allows a targeted Da condition of unity to be achieved and thus facilitates the production of submicron particles even at lower mixing intensities, which require lower energy inputs (Matteucci et al. 2006). A summary of how different process parameters can compensate for lower Re conditions to yield submicron particles is shown in Table 12.7.

Matteucci et al. further explored the range of mixing intensities capable of producing Itz nanoparticles stabilized with P127, ranging from simply pouring the organic into the aqueous solution to drop-wise addition to syringe injection, in addition to the use of high-velocity jets. In all cases, the aqueous phase was mixed using a magnetic stir bar (~500 rpm) to enhance heat and mass transfer during mixing of the organic and aqueous phases. As shown in Table 12.8, submicron particles may still be produced when the organic phase is poured or added drop-wise into the aqueous phase, although a sizable percentage of micron-sized particles were also obtained. These lower-energy, and thus poorer-mixing, conditions likely produce smaller degrees of local supersaturation, resulting in slower nucleation compared to the syringe and

In each case, an Itz loading of 86% w/w and a suspension concentration of 8.9 mg/mL was achieved, with the P127 placed in the aqueous phase only (1.67 mg/mL). Adapted from Matteucci et al. (2006)

high-velocity jet addition techniques. This hypothesis is corroborated by the lower calculated nucleation rates for the lower-energy mixing techniques, as determined using the MSMPR/population model. Interestingly, the addition of the organic solution by syringe at a high organic flow rate of 130 mL/min yielded particles of comparable size to those produced using high-velocity jets, where the organic flow rate was 10 mL/min. Additionally, because the same solvent/stabilizer system was used in all cases, growth rates were relatively similar, with slightly lower calculated growth rates for the syringe and high-velocity jet techniques, attributed to more efficient particle stabilization due to enhanced diffusion of stabilizers to particle surface.

The ability of the AP process to form nanoparticles using low-energy mixing intensity methods has been further demonstrated in several other reports. Rasenack and Muller (2002) showed that, despite the organic drug solution being merely poured into the aqueous phase, Itz nanoparticles were produced when the appropriate stabilizer was selected. In the case of Itz, stabilizing agents containing cellulose ethers with alkyl-substituents, such as methyl cellulose (MC), methylhydroxyethyl-cellulose (MHEC), and hydroxypropylmethylcellulose (HPMC), effectively protected against particle growth to maintain submicron particle sizes. On the other hand, more hydrophilic stabilizers, such as dextran, polyvinylalcohol, polyvinylpyrrolidone, hydroxyethyl starches (HES), and polar substituted cellulose ethers (hydroxyethyl celluloses (HEC) and hydroxypropyl celluloses (HPC)), yielded micron-sized particles under similar operating conditions (Fig. 12.19). These results indicate that the stabilizer must interact sufficiently with the newly formed surface of the poorly water-soluble compound in order to provide an efficient barrier to particle growth. In the cases of MHEC and MC, the methoxyl and hydroxy propyl groups adsorb onto hydrophobic surfaces (Daniels and Barta 1994). Although HPMC is relatively hydrophilic, it is sufficiently hydrophobic to facilitate adsorption onto hydrophobic particle surfaces (Chang and Gray 1978). The ability of HPMC to efficiently stabilize Itz nanoparticles was further explored by examining

Fig. 12.19 Particle size of itraconazole (Itz) particles produced by AP stored as a dispersion 24 h after precipitation. Concentration of stabilizer in water was 0.025% w/w. Data from Rasenack and Muller (2002)

Fig. 12.20 Influence of different concentrations of HPMC 4000 on the size of itraconazole (Itz) particles produced by AP. Particles were stored as a dispersion and sizes were measured 24 h after precipitation. Data from Rasenack and Muller (2002)

the range of HPMC concentrations required for stabilization. A minimum HPMC concentration of 0.025% in the aqueous reservoir was required to stabilize 600-nm Itz particles, under the experimental conditions used by Rasenack and Muller (~30/1 HPMC/Itz, organic solution poured into aqueous solution). Higher HPMC concentrations did not further reduce particle sizes due to the nature by which particles are stabilized in AP, where passivation of the particle surface indicates maximum stabilization (Fig. 12.20). Similar results were observed when HPMC was used to stabilize ketoconazole particles produced by AP under similar operating parameters (Rasenack and Muller 2002). Fenofibrate (~320 nm in diameter) stabilized by a combination of sodium dodecyl sulfate (SDS) and HPMC (Hu et al. 2011) and spiro-lactone nanoparticles (200–400 nm in diameter) stabilized with HPMC have also been prepared by AP (Dong et al. 2009), where the organic solution was rapidly injected into the aqueous phase using a pipette or syringe. In both studies, the organic and

Fig. 12.21 The effect of aging time on the size of freshly precipitated fenofibrate drug particles in dispersion under stirring conditions at the rate of 600 rpm. Reprinted from Hu et al. (2011). Copyright 2011 with permission from Elsevier

aqueous phases were also pumped into a static mixer, which consists of a chamber containing several baffles to facilitate mixing between entering fluids (Hu et al. 2011; Dong et al. 2010; Gassmann et al. 1994). Resultant fenofibrate and spiro lactone particles were of comparable size, although slightly larger, than those prepared when the organic phase was introduced by injection (~330 and 500 nm for fenofibrate and spiro lactone, respectively), indicating relatively efficient mixing within the static mixer. In the case of the fenofibrate particles, continued monitoring of particle size showed that the freshly precipitated particles grew over time if left in the suspension, up to four times the initial size in just 10 min (Fig. 12.21) (Hu et al. 2011). The particle growth may be driven by condensation of dissolved drug molecules and/or Ostwald ripening due to the organic solvent still present in the aqueous suspension. In response to these challenges, modifications to the AP process have been developed to facilitate nanoparticle production as well as to maintain particle size after precipitation by minimizing particle growth and are discussed in the next section.

12.3.1 Recent Trends in AP Processes

12.3.1.1 Flash Nanoprecipitation (FN) Process

To facilitate the production of amorphous nanoparticles for enhanced dissolution of poorly water-soluble drugs, flash nanoprecipitation (FN) aims to minimize mixing times between the solvent and antisolvent, down to millisecond timescales, using

Fig. 12.22 Schematic of confined impinging jet (CIJ) apparatus: A solvent jet, in which the poorly water-soluble drug and stabilizers are dissolved, and an antisolvent jet containing stabilizers are impinged against each other to facilitate mixing of the two solutions. High-velocity impingement promotes rapid mixing within the chamber to facilitate rapid particle precipitation. Reprinted with permission from Zhu et al. (2007). Copyright (2007) American Chemical Society

a custom-designed confined impinging jet (CIJ) mixer. In a CIJ mixer, a solvent stream and an antisolvent stream are introduced into a mixing chamber at turbulent jet velocities, in such a manner that the two streams are collinear and thus collide with each other. Mixing within impinging jets produces a region of high-energy dissipation, as the kinetic energy of the jet streams is converted to turbulent motion through collision and redirection of fluid flow within a confined volume. These high-energy dissipation regions rapidly reduce the scale of segregation between the two fluid streams, thus facilitating rapid nucleation. The mixing chambers in the FN process must be large enough for the high-energy dissipation regions to form, but limited in volume to avoid significant bypassing of any fluid from intense mixing (Johnson et al. 2006; Johnson and Prud'homme 2003a, b, c). A schematic of the FN process is shown in Fig. 12.22.

Mixing energies characterized by Re up to 3,000 have been reported for CIJ mixers, corresponding to a characteristic mixing time, τ_{mix} , of 5 ms, when jet diameters, jet velocities of the fluid stream, and chamber size have been optimized (Johnson and Prud'homme 2003a, b, c). According to Johnson and Prud'homme, optimal performance of the FN process is achieved when τ_{mix} values are less than 100 ms (Johnson et al. 2006). These low τ_{mix} values promote nanoparticle production, as seen in (12.10), as well as narrow PSDs. In FN studies, Johnson and Prud'homme stress the importance of not only comparing τ_{prec} of the drug to τ_{mix} but also matching τ_{prec} of the drug with τ_{prec} of the stabilizer, especially in the case of polymeric stabilizers. When the precipitation times for the drug and stabilizer are manipulated to match one another, the hydrophobic portion of the stabilizer is designed to

Fig. 12.23 Schematic of a multi-inlet-vortex mixer (MIVM), used to facilitate efficient mixing of multiple feed streams with unequal flow rates into the confined impinging jet (CIJ) mixer. Reprinted from Liu et al. (2008). Copyright 2008 with permission from Elsevier

precipitate onto the surface of the drug particle at the onset of nucleation, thus deterring further particle growth beyond nucleation sizes. Moreover, the proper selection of stabilizers can act as a nucleation initiator to further control nanoparticle production. Characteristic precipitation times may be adjusted by tuning stabilizer properties, such as molecular weight (MW) and the size ratio of hydrophilic to hydrophobic moieties, as well as the drug feed concentration. To demonstrate the importance of stabilizer selection in FN, β -carotene particles stabilized by polystyrene (PS) (2 K)-*b*-polyethylene glycol (PEG) (5 K) and polycaprolactone (PCL) (3.6 K)-*b*-PEG (6 K) were compared. Particles stabilized with PS-*b*-PEG, possessing a drug potency of 66% w/w, were ~ 100 nm in diameter, while those stabilized with PCL-*b*-PEG required higher stabilizer levels to achieve an average particle size of 100 nm, reducing the drug potency to 18% w/w. The reduced effectiveness of the PCL-*b*-PEG polymer to stabilize the β -carotene particles was attributed to the lower melting point of the PCL, which may have facilitated aggregation between the particles (Zhu et al. 2007). FN has also reported the successful production of CsA nanoparticles (~ 300 nm) stabilized by a combination of dextrose monohydrate and lecithin at a drug potency of 30% w/w (Chiou et al. 2008a, b). Methods, such as vacuum distillation or spray drying, were required to remove the organic solvent from the final suspension in order to minimize aggregation of particles after precipitation.

Recent research on the FN process has focused on the addition of a multi-inlet-vortex mixer (MIVM) to FN (schematic shown in Fig. 12.23) to allow for efficient mixing of multiple streams with unequal flow rates, which has been found to be a requirement for some systems to achieve optimal nano-precipitation conditions. To validate that sufficient mixing is achieved within the MIVM, Liu et al. developed a computation fluid dynamics (CFD) simulations program to emulate flow behavior within the MIVM (Liu et al. 2008). The simulation was validated using a model experiment, involving a parallel, competing reaction system, in which product yields were measured to give an indication of mixing intensity. Excellent correlation between the simulation and experimental data was found, providing validation of mixing performance within the MIVM, as well as a useful tool to optimize process parameters for nanoparticle production in future studies (Liu et al. 2008). In the case of the production of paclitaxel nanoparticles by FN, submicron particles could not be produced using only PCL(3 K)-*b*-PEG (5 K) as the stabilizer. However, the introduction of a PCL homopolymer in addition to the block copolymer using the MIVM-modified CIJ mixer yielded particles ranging from 80 to 145 nm in

Fig. 12.24 Schematic of controlled precipitation process. Adapted from Rogers et al. (2004)

diameter, depending on the MW of the PCL homopolymer (Johnson et al. 2006). The scalability of this new mixer was demonstrated for different chamber geometries and sizes (Johnson et al. 2006).

12.3.1.2 Controlled Precipitation (CP) Process

To minimize particle growth after precipitation, the controlled precipitation (CP) process incorporates a semicontinuous solvent removal step, such as vacuum distillation, after the solvent and antisolvent are mixed together (Fig. 12.24). By incorporating the solvent removal step in-line with the process to remove excess solvent immediately after precipitation instead of in a separate step, substantial levels of particle growth may be minimized. In CP, solvent removal is typically performed within a wiped film evaporator to maximize the available surface area over which solvent evaporation may occur, as well as to reduce any foaming that might have occurred during processing, given the high amounts of surfactants required for stabilization in some cases (Rogers et al. 2004; Hitt et al. 2003, 2006). Rapid removal of a significant portion of the solvent markedly reduces the solubility of the drug in the mixed solvent. Thus, particle growth by condensation of dissolved drug molecules and Ostwald ripening may be greatly minimized.

Danazol and naproxen particles prepared by CP were well below 1 μm in diameter, 200 and 270 nm, respectively, as long as the operating temperature was kept at 3°C (Rogers et al. 2004). Measured residual solvent levels, methanol for both cases, in the aqueous suspension after the solvent removal step ranged between 70 and 380 ppm, well below the International Conference on Harmonization (ICH) guidelines for pharmaceuticals for human use (Rogers et al. 2004). Lower precipitation temperatures corresponded to lower residual methanol levels, in addition to favoring nanoparticle production. A significant increase in particle size (up to an order of magnitude) and polydispersity (from unimodal to bi- and tri-modal distributions) was observed when the precipitation temperature was increased to 25 and 50°C (Rogers et al. 2004), consistent with the AP work by Matteucci et al. (2006). Additionally, the ability of the CP process to produce high-potency nanoparticles has been demonstrated for several poorly water-soluble drugs, including Itz stabilized by HPMC (up to 94% w/w drug

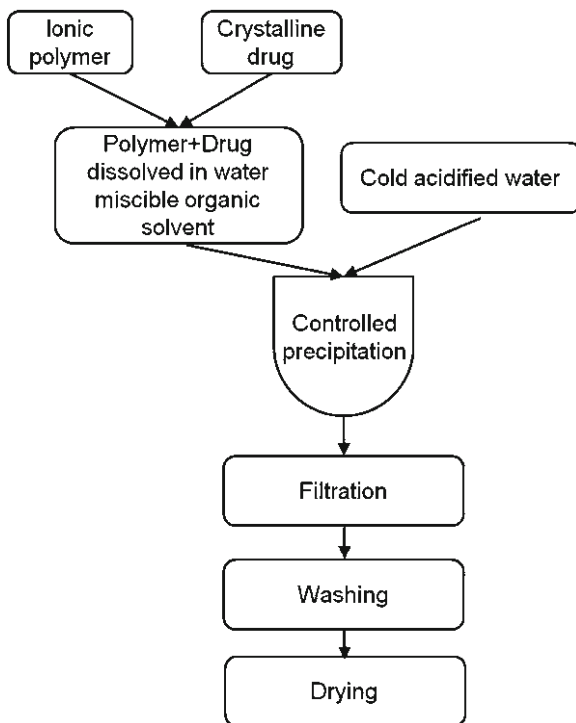

potency for particles 90–355 nm in diameter) (Matteucci et al. 2007), cyclosporin A (CsA) stabilized using Tween 80 (91% w/w drug potency for particles 300 nm in diameter) (Tam et al. 2008), and repaglinide (REP) stabilized with HPMC (50% w/w drug potency for particles 650 nm in diameter) (Sinswat et al. 2007), as expected since the particle formation and stabilization mechanism for CP are similar to those of AP. Scalability of the CP process was also demonstrated by the successful production of a 1-kg batch of naproxen particles (Rogers et al. 2004).

Another important aspect of the CP process is its high propensity to produce amorphous particles, due to the rapid nucleation and stabilization rates generated during the precipitation process. As seen in the Noyes–Whitney equation (12.1), higher metastable solubilities of high-energy amorphous compounds, C_{sat} , relative to crystalline compounds, provide a larger concentration gradient to drive particle dissolution. Production and stabilization of an amorphous morphology require rapid particle stabilization during the precipitation process, similar to the conditions required for stabilization of small particle sizes. The same principles are applied to control particle morphology, as the goal is to stabilize the particle before the molecules can arrange into a crystal structure. Controlled precipitation of Itz (Matteucci et al. 2007), CsA (Tam et al. 2008), and REP (Sinswat et al. 2007) have yielded nanoparticles possessing an amorphous morphology, which contributed to their enhanced dissolution rates over the bulk, crystalline drug particles.

12.4 Precipitation into Acid: Microprecipitated Bulk Powder (MBP) Formulations

Scientists at Roche have recently presented a modified approach to AP, in which a poorly water-soluble drug compound is stabilized by an ionic polymer via precipitation in an acid bath (Albano et al. 2002). Due to the proprietary nature of this technique, only a simplified process flow diagram, illustrated in Fig. 12.25, is available in the public domain. The drug and ionic polymer are dissolved in an organic solution, which is then added to a cooled acid bath to initiate nucleation of the drug particles. The ionic nature of the stabilizer is critical for effective “microprecipitation” of “nanosized” drug domains, which are claimed to be molecularly dispersed throughout a polymer matrix. The resultant powder has been termed a “microprecipitated bulk powder” (MBP). Amorphous morphologies have also been formed under sufficiently rapid stabilization conditions. Ionic polymers with a MW of at least 80,000 Da and a glass transition temperature, T_g , $>50^\circ\text{C}$ have been found to promote efficient stabilization of submicron, amorphous drug domains by this precipitation technique. The acidic aqueous bath is likely needed to elicit the desired charge on the polymer to promote a strong interaction between the polymer and the newly formed drug surfaces (Shah et al. 2010). This technology has demonstrated scalability and is currently being used for the production of several Biopharmaceutical Classification System Class II (low-solubility, high-permeability) and Class IV

Fig. 12.25 Process train for production of microprecipitated bulk powder (MBP) formulation. Adapted from Shah et al. (2010)

(low-solubility, low-permeability) compounds in phase I–II clinical trials (Shah et al. 2010; Flaherty et al. 2010).

12.5 Nanoparticle Recovery

Whereas a wide variety of techniques have been developed to produce aqueous dispersions of nanoparticles, the recovery of the nanoparticles in the solid state remains a formidable challenge. Common techniques for solvent removal include spray drying, freeze drying (i.e., lyophilization), and ultrafiltration (Limayem et al. 2004; Torino et al. 2010; Matteucci et al. 2008). Particle growth may occur in these processes, as the nanoparticles are concentrated during solvent removal. Concentration of nanoparticles may occur by various pathways, depending on the state of solvation of the polymeric stabilizer during solvent removal, as shown in Fig. 12.26. Process conditions, such as temperature, salinity of the nanoparticle dispersion, or rate of solvent removal, may be manipulated to influence flocculation behavior of the nanoparticles. In spray drying, dense flocs, which do not redisperse well back to primary nanoparticles, may be produced because the increase in nanoparticle concentration within the shrinking, evaporating droplet raises collision rates and the propensity for Ostwald ripening. Additionally, the high temperatures

Fig. 12.26 Floc structure as a function of polymer solvation and particle volume fraction, Φ . Polymer solvency diminishes with an increase in salinity or temperature. Adapted and reprinted with kind permission from Springer Science+Business Media: Matteucci et al. (2008), copyright 2008

required for sufficient solvent evaporation, typically greater than 90°C , have been shown to desolvate some polymeric stabilizers and can further facilitate the formation of large, dense flocs (Heimenz and Rajagopalan 1997; Larson 1999; Napper 1983). Similarly, for freeze drying and ultrafiltration, the increase in nanoparticle concentration and potential changes in solvent quality with solvent removal may also produce dense flocs with the same limitations. These particle recovery techniques are energy intensive and may require long processing times (freeze drying and ultrafiltration).

An alternative approach to nanoparticle recovery is to form large, open flocs of primary nanoparticles that may be more efficiently filtered than isolated primary particles, dried, and then redispersed upon dosing (Matteucci et al. 2008; Chen et al. 2009; Miller et al. submitted). Aqueous suspensions (500 mg drug in 50 ml solution) of large, open flocs can be filtered in minutes to obtain a dry powder (Matteucci et al. 2008; Chen et al. 2009), compared to hours for recovery of primary nanoparticles by filtration (typically $\sim 0.03 \text{ mL/min cm}^2$) (Matteucci et al. 2008). Flocculation of primary particles may be induced by adding a salt to raise the ionic strength of the solution (Matteucci et al. 2008; Chen et al. 2009) or by changing the pH (Miller et al. submitted), in each case to desolvate the polymer stabilizer on the particle surface. In the case of flocculation with salt, the loss of hydration of the polymer leads to a loss in steric stabilization of the nanoparticles. At the cloud point of the polymer, steric stabilization becomes weak and the polymer-coated nanoparticles flocculate. Solvation of polyethylene oxide (PEO)-, PVP-, and HPMC-based stabilizers are known to decrease with an increase in salinity or temperature (Pandit et al. 2000; Xu et al. 2006; Pang and Englezos 2002). Sodium sulfate (Na_2SO_4) has been used to

Fig. 12.27 Scanning electron microscopy (SEM) images of salt-flocculated Itz nanoparticle dispersions stabilized with different amounts of excipient. Reprinted with kind permission from Springer Science+Business Media: Matteucci et al. (2008), copyright 2008

flocculate crystalline naproxen nanoparticles stabilized by PVP- or PEO-based polymers (Chen et al. 2009) and Itz nanoparticles stabilized by mixtures of poloxamer 407 (P407) and HPMC (Matteucci et al. 2008). This process is best illustrated by “Path A” in Fig. 12.26, where the addition of salt rapidly decreases the polymer solvation and sticky collisions between unstabilized nanoparticles produce open flocs. The strong van der Waals attraction between particles “locks in” the open floc structure and inhibits rearrangement of the particles, as indicated by microscopy images (Fig. 12.27) and calculated fractal dimensions < 2 . The flocs are essentially formed by diffusion-limited colloid aggregation. In contrast, slow induction of polymer desolvation (“Path B”) allows particles to rearrange into more energetically favorable dense flocs. Recovery methods in which nanoparticle volume fractions increase via solvent reduction, as in spray (“Path D”) and freeze drying (“Path C”) and ultrafiltration (“Path C”), also tend to form denser flocs that may not readily redisperse to primary particles after drying, as compared to flocs produced by “Path A.” Moreover, flocculate formation may be tuned to balance requirements for drug loading (drug/excipient ratio within the particles) versus process yields by controlling the nature and composition of the polymer stabilizers and the amount of salt used to induce flocculation, which was demonstrated during flocculation of naproxen (Chen et al. 2009) and Itz nanoparticles (Matteucci et al. 2009).

Upon redispersion of the flocs in a good solvent, or during drug administration in physiological fluids, the primary nanoparticles within the floc are highly accessible to the solvent and thus readily redisperse, a behavior indicative of loose, open flocs. Itz and naproxen powders that were dried after salt flocculation have been shown to redisperse to their original freshly precipitated particle sizes (~ 300 nm diameter) (Matteucci et al. 2008, 2009; Chen et al. 2009) and drug yields after filtration were as high as 99% (w/w recovered/input drug), compared to typical recoveries of 50–70% for spray-dried materials (Nguyen et al. 2004; Maa et al. 1999). Furthermore, salt-flocculated Itz particles maintained their amorphous morphology from the original precipitated dispersions, as shown by differential scanning calorimetry

(DSC) and dissolution studies, whereas the Itz particles crystallized when recovered by spray drying (Matteucci et al. 2008).

By a similar principle, electrosteric stabilization of nanoparticles coated with charged polymers may be manipulated by adjusting pH to neutralize a sufficient fraction of the charges. Itz nanoparticles stabilized by a by adjusting pH-sensitive methacrylate-based polymer, Eudragit L100-55, were flocculated rapidly by lowering the solution pH to 2.5 with hydrochloric acid (HCl) to protonate the carboxylate groups on the polymer (Miller et al. submitted). As described above, the rapid and strong increase in interparticle attraction due to the pH reduction under constant volume fraction resulted in relatively large open flocs (Matteucci et al. 2008; Chen et al. 2009). As observed for salt flocculation of Itz nanoparticles, crystallization of Itz was minimal, since the large flocs were rapidly filtered at room temperature (Matteucci et al. 2008, 2009). Upon redispersion at pH 6.8, solvation of the enteric polymer resulted in only a slight increase in size of the EL100-55-stabilized nanoparticles (Miller et al. submitted). Preservation of the amorphous morphology after the pH-flocculation process was verified by the achievement of higher in vivo bio-availability in rats upon oral administration of the flocculated powders relative to a commercial Itz solid dispersion (Sporanox) (Miller et al. submitted). An advantage of the pH flocculation process, relative to previous salt flocculation studies, is the potential for a decrease in salt impurities in the final product.

For the flocculation/filtration process, the ability to operate at low temperatures and constant particle volume fractions (flocculation induced without solvent reduction), as well as rapid removal of solvent, inhibited both growth and crystallization of the amorphous primary nanoparticles and promoted the preservation of the highly open floc structures. Another advantage of this technique is that large amounts of stabilizer may be used in the particle formation stage to promote the production of nanoparticles without impacting final drug loadings because any excess, unadsorbed stabilizers are removed during filtration, thus facilitating high drug/polymer ratios in the powder, with drug loadings in the range of 80–99% (Matteucci et al. 2008, 2009; Chen et al. 2009; Miller et al. submitted). Thus, the flocculation/filtration recovery process offers a simple, efficient alternative to traditional nanoparticle recovery techniques capable of yielding nanoparticle assemblies with high drug loadings and process yields while preserving amorphous morphologies.

12.6 Conclusions

Precipitation processes possess several advantages for nanoparticle production over conventional top-down approaches, such as milling and homogenization, as they offer enhanced control of morphology and PSD with minimal complications of contamination and product degradation. The ability of different precipitation processes, in which SCFs and organic solvents were utilized as both solvents and antisolvents, to reproducibly yield nanoparticles for a wide range of pharmaceutical materials has been demonstrated. The strengths and weaknesses of the different

precipitation processes have also been highlighted to aid in screening the suitability of a particular process for different drug systems. Another important trend in precipitation research that has been highlighted in this chapter is the emphasis on understanding the fundamental mechanisms that drive these precipitation processes, in order to facilitate successful scale-up of the precipitation techniques and promote their utility in commercial settings. Increased knowledge of these precipitation technologies benefits not only the microparticle/nanoparticle production fields but also areas of drug encapsulation (Rodrigues et al. 2004; Li et al. 2005; Young et al. 1999) and cocrystallization (Padrela et al. 2009) and will be of general interest for all sectors involving particle engineering. Novel particle recovery processes, based on controlled flocculation/filtration of primary nanoparticles, have also been discussed as an efficient means to harvest nanoparticles after precipitation, making precipitation processes more attractive and feasible for industrial production.

Method Capsule 1

Precipitation by GAS

Based on the method reported by Muhrer et al. (2003).

Objective

- To obtain nanoparticles using GAS precipitation

Materials and Equipment

- Poorly water-soluble drug (proprietary)
 - MW = 600 g/mol
 - $T_{\text{melt}} = 200^{\circ}\text{C}$
 - Solubility ($T = 25^{\circ}\text{C}$): 3 mg/mL in water; 18.5 mg/mL in acetone or acetonitrile; insoluble in CO_2
- Solvent: Ethanol
- Antisolvent: CO_2
- Cryostat to subcool CO_2 from reservoir tank
- Pump to transfer CO_2 from reservoir tank to precipitator
 - Gilson HPLC pump (low/intermediate flow rates)/Haskel pneumatic piston pump (high flow rates)
- Heater coil (via water bath) to preheat CO_2 feed to process temperature before entering precipitator
- Precipitation vessel (1 L)
 - Equipped with a mechanical stirrer
 - Sinter metal filter connected to the outlet tube

- Pump to transfer organic solution to precipitation vessel
- Oil bath ($T=80^{\circ}\text{C}$) to heat the fluid line exiting the precipitation vessel (to avoid blockage)

Method

- The poorly water-soluble drug was dissolved in 75–150 mL in ethanol at concentrations between 50% and 90% of the solubility at 25°C
- Drug/ethanol solution was pumped into the precipitator
- CO_2 (preheated to 25°C) was fed into the precipitator at 18–360 mL/min until the precipitator was full
- Contents in precipitator stirred at 500 rpm during CO_2 filling and for 30 min after the precipitator was filled
- Exit valve on precipitator was opened to flush out solvents and fresh CO_2 was pumped through (20 mL/min) for at least 5 h to remove any residual organic solvent from powder
- Dry powder harvested from metal filter

Results

- SEM indicated that spherical particles with a moderate level of agglomeration were produced
 - Lower CO_2 flow rates (2–18 mL/min):
 - Produced bimodal particle-size distributions (PSD)
 - 1–6- μm diameter
 - Higher CO_2 flow rates (240–360 mL/min):
 - Produced unimodal PSDs
 - 500–720-nm diameter
- X-ray powder diffraction indicated that the resultant particles were amorphous
- Gas chromatography determined residual solvent levels were below 0.01 wt%

Method Capsule 2

Precipitation by PCA

Based on the method reported by Reverchon et al. (2003b)

Objective

- To obtain nanoparticles using PCA precipitation

Materials and Equipment

- Amoxicillin
- Solvent: *N*-methyl 2-pyrrolidone (NMP)

- Antisolvent: CO₂
- Shell-and-tube heat exchanger to cool feed to CO₂ reservoir
- Diaphragm pump to transfer CO₂ from reservoir to dryer
- CO₂ dryer (113 L) with silica gel as the drying medium to remove trace amounts of water from CO₂ reservoir, prior to entering precipitator
- Heat exchanger to heat CO₂ to supercritical conditions
- Piston pump to transfer organic solution to precipitator
- Precipitation vessel (5.2 L)
 - Internal stainless steel basket to collect powder
 - Temperature maintained by a water jacket
- Coaxial injector: internal tube i.d.=3 mm fitted with a 0.5-mm diameter nozzle; annulus i.d.=8.5 mm
- Liquid separator (13 L) heated with water jacket to separate and collect solvent and antisolvent

Method

- PCA operation conducted in a continuous mode, where CO₂ exiting the precipitator was recirculated and the solvent exiting the liquid separator was purged and stored
- CO₂ was pumped into the precipitator at a constant flow rate (0.6–2.0 kg/h), passing through a heat exchanger to heat the CO₂ to 40°C, until steady-state conditions were achieved. The precipitator pressure was set to 150 bar
- Pure NMP was fed into the chamber through the coaxial injector for a few minutes
- ~100 mL of the amoxicillin/NMP solution (20–100 mg/mL amoxicillin) was then fed into the chamber at the same flow rate as the pure NMP
- Pure CO₂ continued to flow through the precipitator for a predetermined amount of time, correlating to the calculated time required for 99 wt% elimination of NMP
- Dry powder was harvested from the internal basket inside precipitator

Results

- 90 wt% drug recovery, as calculated compared to initial drug amount in organic feed solution
- Amorphous particles produced
- SEM indicated that spherical particles were produced
 - Lower drug feed concentrations (20 mg/mL):
 - Produced more narrow particle-size distributions (PSD)
 - 200–600-nm diameter
 - Higher drug feed concentrations (100 mg/mL):
 - Produced more broad PSDs
 - 500–1,800-nm diameter

Method Capsule 3

Precipitation by RESS

Based on the method reported by Turk et al. (2002).

Objective

- To obtain nanoparticles using RESS precipitation

Materials and Equipment

- β -sitosterol
- Solvent: CO₂
- Extraction column
- Diaphragm pump to transfer CO₂ into extraction column
- Water bath to heat extraction column
- Capillary nozzle (i.d. of 50 μm , length of 50 μm) – heated to 115–145°C to prevent clogging during atomization

Method

- CO₂ from the reservoir was pressurized to a pre-expansion pressure of 20–30 MPa
- The scCO₂ was then pumped through a water bath heated to 75–145°C (pre-expansion temperature) to the extraction column
- The extraction column, which was also immersed in the water bath ($T=75\text{--}145^\circ\text{C}$), was packed with the drug and the CO₂ solution became saturated with the drug
- The scCO₂–drug solution was then expanded through a heated, capillary nozzle into an expansion chamber, for powder collection

Results

- SEM indicated that roughly spherical particles with moderate agglomeration were produced. Primary particles were ~150 nm in diameter
- Particle size was independent of pre-expansion temperature

Method Capsule 4

Precipitation by EPAS

Based on the method reported by Chen et al. (2002)

Objective

- To obtain nanoparticles using EPAS precipitation

Materials and Equipment

- Cyclosporin A (CsA)
- Stabilizers: Myrj 52, Tween 80, polyvinylpyrrolidone (PVP 40 T)

- Solvent: dichloromethane (DCM)
- Antisolvent: deionized water
- EPAS apparatus: stainless-steel coiled tube (3 m length, 1/16" o.d. \times 0.030" i.d.) housed within a plastic water jacket (24" length, 1-1/2" o.d.)
- Temperature controller to circulate and heat water through the EPAS apparatus's water jacket
- Nozzle: stainless-steel tube (10" length, 1/16" o. d. \times 0.030" i.d.) that was cut with a wire cutter to produce a thin, elliptical slit. The tapered section of the orifice was ~0.5 mm in length and the tip was filed down (to adjust the thickness of the slit) until desired atomization was achieved, generally characterized by a pressure drop across the nozzle orifice of ~20 MPa for flow rates of 1 mL/min
- HPLC pump to feed solvent into the antisolvent
- Water bath to heat aqueous surfactant solution
- Separatory funnel (125 mL)
- Lyophilizer

Method

- Solutions of 1–5% w/v CsA in DCM and aqueous solutions of 1% w/v surfactant were prepared
- The aqueous surfactant solution (50 mL) was poured into the separatory funnel, which was then submerged in a water bath ($T=75^{\circ}\text{C}$)
- The nozzle of the EPAS apparatus was submerged ~2 cm below the surface of the aqueous solution
- The organic drug solution was fed into the aqueous surfactant solution at a flow rate of 1 mL/min until a drug concentration of 1% w/v CsA (10 mg/mL) was achieved in the aqueous suspension
 - Turbulence from the atomization of the organic solution was sufficient to facilitate mixing with the aqueous phase
 - To suppress the surfactant foam produced by the intense mixing of the organic and aqueous phases, nitrogen was blown across the top of the separatory funnel
- To dry the particles, the suspensions were flash frozen in liquid nitrogen and lyophilized to powders

Results

- Particle sizing results were determined by dynamic light scattering
 - Block copolymer (Myrj 52, Tween 80) versus homopolymer (PVP 40 T) stabilizers
 - Myrj and Tween-stabilized particles were about half the size of PVP-stabilized particles (530–630 nm vs. 1,080 nm, respectively)
 - 1% w/v versus 5% w/v drug concentration in organic feed

- Higher drug concentrations in the feed yielded smaller particles (~340 nm for Mryj and Tween-stabilized particles and ~600 nm for PVP-stabilized particles)
- 86–96% drug recoveries achieved, as calculated compared to the initial drug amount in feed solution
- X-ray powder diffraction indicated that the resultant particles were amorphous
- Gas chromatography determined residual solvent levels in powders were below 0.0004 wt%

Method Capsule 5

Flash Nanoprecipitation (FN)

Based on the method reported by Chiou et al. (2008b)

Objective

- To obtain nanoparticles using FN

Materials and Equipment

- Cyclosporin A (CsA)
- Stabilizers: lecithin and dextrose monohydrate
- Solvent: ethanol
- Antisolvent: deionized (DI) water
- Two syringe pumps (50 mL syringe)
- Confined liquid impinging jet (CLIJ) mixer

Method

- CsA (0.7 g) was dissolved in ethanol (10 mL) and loaded into one of the syringe pumps
- An aqueous solution (30 mL) of lecithin (0.3 g) and dextrose monohydrate (1.5 g) was prepared and loaded into the other syringe pump
- The syringe pumps containing the organic and aqueous solutions were fed into the CLIJ mixer at 40 mL/min and 120 mL/min, respectively, until a total of 10 mL of organic solution and 30 mL of aqueous solution had been dispensed
- The resultant aqueous suspension was quenched in 50 mL of DI water

Results

- Particle sizing results were determined by laser light scattering
 - Average particle diameter: 294 nm (span 1.017, GSD 1.46)
 - After drying, the particles were a mean diameter of approximately 260 nm
- Scanning electron microscopy demonstrated that the particles were spherical

Method Capsule 6

Precipitation by CP

Based on the method reported by Matteucci et al. (2007)

Objective

- To obtain nanoparticles using CP

Materials and Equipment

- Itraconazole (Itz)
- HPMC E5
- Solvent: 1,3 dioxolane
- Antisolvent: deionized water
- Syringe to inject organic solution into a mixer
- Mixing apparatus to mix organic and aqueous phase
- Vacuum distillation apparatus equipped with a wiped film evaporator
- Pump to transfer aqueous suspension from mixing apparatus to vacuum distillation apparatus
- Lyophilizer

Method

- Solutions of Itz (3.3% w/w) in 1,3 dioxolane and aqueous solutions of HPMC (various concentrations) were prepared
- The aqueous phase was maintained at $T_{\text{precip}} = 3^{\circ}\text{C}$
- The organic phase was rapidly introduced to the aqueous phase using a mixing apparatus (may be accomplished by using a syringe to inject the organic phase into the aqueous phase, as the aqueous phase is being stirred by a magnetic stir bar)
- The newly formed aqueous suspension was pumped to the vacuum distillation apparatus, where the methanol content in the slurry was reduced
- To dry the drug particles, the aqueous suspensions were frozen in liquid nitrogen and then lyophilized to powders

Results

- Particle sizing results were inferred from BET surface area measurements
 - Lower drug/stabilizer ratios resulted in smaller particle sizes
 - Average particle sizes were 90, 200, 270, and 355 nm for a 1/2, 1/1, 2/1, and 4/1 Itz/HPMC ratio, respectively
- Scanning electron microscopy demonstrated that the particles were spherical and confirmed particle-size estimates from BET surface area measurements
- Contact-angle measurements demonstrated that the HPMC was primarily concentrated on the particle surface, and not within the interior of the particle
- X-ray powder diffraction and differential scanning calorimetry indicated that the resultant particles were amorphous

Method Capsule 7

Salt Flocculation for Nanoparticle Recovery

Based on the method reported by Matteucci et al. (2008)

Objective

- To recover nanoparticles produced by precipitation processes using salt flocculation

Materials and Equipment

- Aqueous suspension of itraconazole (Itz) nanoparticles, prepared by controlled precipitation, stabilized with a combination of both Pluronic F127 (P127) and HPMC E5 (8:1:2 Itz:P127:HPMC)
- Sodium sulfate salt, anhydrous (Na_2SO_4)
- Type P2 filter paper (area: 95 cm², pore size: 1–3 μm)
 - Filter paper cut into a circle with a 11-cm diameter
- Vacuum pump

Method

- At room temperature, a 1.5-M solution of Na_2SO_4 was added to an aqueous nanoparticle dispersion (10 mg/mL Itz) at a ratio of 12:5 v:v (salt solution:dispersion) and allowed to sit for 3 min
 - Within seconds, flocs formed and were observed to take up the entire volume of the nanoparticle dispersion/salt solution mixture.
 - After 3 min, larger flocs formed and the flocs creamed, taking up ~20% of the original volume
- The flocculated suspension was filtered through the filter paper under vacuum until water was no longer observed on top of the filter cake (typically <8 min for ~200 mL of the nanoparticle suspension/salt solution mixture)
- An aqueous HPMC solution (30 mL at the same concentration as the aqueous phase during nanoparticle precipitation) was cooled in an ice bath. Immediately after filtration, the chilled HPMC solution was used to rinse the filter cake
 - For the 8:1:2 Itz:P127:HPMC particles, a 2.5-mg/mL HPMC solution was used
- The filter cake was dried at room temperature and atmospheric pressure overnight
- Dried powders were gently scraped off the filter paper with a spatula

Results

- Static light scattering results showed that the flocculated nanoparticles redispersed back down to near-original particle sizes in DI water

- Before flocculation: $D_{10}/D_{50}/D_{90}$ were 110/340/2,260 nm
- After salt flocculation and redispersion in water with 5 min of sonication: $D_{10}/D_{50}/D_{90}$ were 120/370/1,480 nm
- Scanning electron microscopy images confirm the ~300-nm primary particle sizes reported by light scattering (see Fig. 12.27)
- 94 wt% drug loading (% of drug in dried powder)
- Drug yields of ~90% were obtained, as calculated compared to the amount of drug in the initial dispersion
- Contact-angle measurements indicated that the stabilizers were concentrated on the particle surface, not within the particle interior
- Temperature-modulated differential scanning calorimetry (mDSC) indicated that primary nanoparticles remained amorphous after salt flocculation

Chapter 13

Emerging Technologies to Increase the Bioavailability of Poorly Water-Soluble Drugs

Justin R. Hughey and James W. McGinity

Abstract The need for novel formulation and process-based techniques to enhance aqueous solubility has increased substantially in recent years. This is primarily due to the limitations of traditional techniques such as physical and chemical stability of the drug substance or the need for toxic solvents that some techniques require. Alternative solubility-enhancement techniques have emerged in recent years to mitigate issues such as these. The purpose of this chapter is to describe emerging technologies for solubility enhancement, allowing the reader to gain an understanding of their utility.

13.1 Introduction

With the advent of high-throughput screening techniques in drug discovery, the number of compounds reaching the formulation development stage has increased drastically (Lipinski et al. 2001; Lipinski 2004). Consequently, this has given rise to a dramatic increase in the number of compounds that exhibit poor water solubility. These drug substances may also exhibit instabilities or other properties that severely limit acceptable formulation and processing techniques. The development of new techniques to improve the bioavailability of compounds such as these has become a major point of interest in the pharmaceutical industry. In recent years, a number of novel formulation and processing techniques have emerged that allow for the successful processing and delivery of these compounds. These techniques can be broadly classified as those utilizing specific equipment or those that are more general and utilize certain types or classes of materials.

Emerging technologies that utilize specific equipment primarily offer novel methods of forming solid dispersions with traditional materials. These technologies offer alternatives to methods such as spray drying and hot-melt extrusion (HME). Specifically, KinetiSol[®] Dispersing (KSD), electrostatic spinning, and ultrasonic compaction are all novel techniques that have recently emerged for the production of solid dispersion systems.

In addition to methods utilized for solid dispersion systems, novel techniques have emerged that utilize guest/host or carrier systems to deliver drug substances. Carrier-based systems identified as being relatively new techniques for the delivery of poorly water-soluble drug substances are polymeric micelles and mesoporous silica. The following sections discuss specific examples of each bioavailability enhancement technique and in what cases they should be utilized.

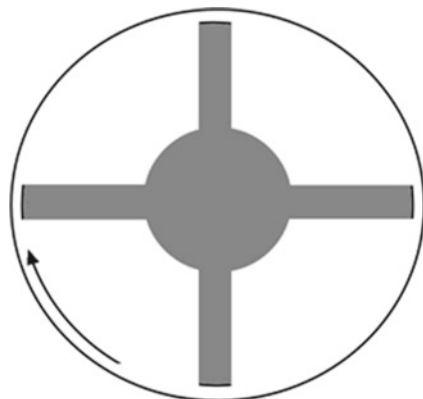

13.2 Equipment-Specific Techniques

Solid dispersions have received a significant amount of interest in the scientific literature as a method to improve the oral bioavailability of poorly water-soluble compounds (Serajuddin 1999; Leuner and Dressman 2000; Breitenbach 2002; Crowley et al. 2007). These systems, originally described by Sekiguchi and Obi, contain at least one drug substance dispersed within an inert carrier in the solid state (Sekiguchi and Obi 1961; Chiou and Riegelman 1971). Amorphous solid solutions, in which the drug is molecularly dispersed in a single phase system, may be prepared by methods that can be broadly classified as being solvent- or fusion-based techniques. Traditional high-throughput manufacturing processes such as spray drying and HME have been used with great success for the production of many solid dispersion systems. However, each technique has inherent disadvantages that may prevent the successful formulation of some compounds.

While the spray-drying process has the advantage of utilizing traditional manufacturing equipment, it relies on the use of potentially toxic solvents which must ultimately be recovered and properly disposed of. Dispersions prepared by spray drying often require extended drying steps in order to reduce residual solvent levels to those outlined in International Conference on Harmonization guidelines. Furthermore, the spray-drying process results in dispersions with relatively low bulk densities requiring additional downstream processes such as roller compaction.

The HME process may not be feasible in cases where the drug substance is thermally labile or shear sensitive. One major disadvantage of this technology is that high temperatures and prolonged residence times are normally required to facilitate the transition from the thermodynamically stable crystalline state to the high-energy amorphous state. Degradation due to thermal exposure has been reported for polymers (El'darov et al. 1996; Crowley et al. 2002; Capone et al. 2007) and many drug substances are known to degrade at elevated temperatures (Follonier et al. 1994; Repka et al. 1999, 2003; Murphy and Rabel 2008). Simply reducing processing temperature to limit degradation may not be feasible due to viscosity and glass-transition

Fig. 13.1 Cross-sectional view of the KinetiSol® Dispersing processing chamber (DiNunzio et al. 2008)

temperature limitations. To circumvent this issue, liquid or solid-state plasticizers may be incorporated into dispersions as a processing aid (Follonier et al. 1994; Repka et al. 1999; Zhu et al. 2002, 2006). While incorporation of a plasticizer does allow for processing at decreased temperatures, it may result in a physically unstable system due to increased molecular mobility (Hancock et al. 1995; Hancock 2002).

Residence times at elevated temperatures in a HME process will vary with processing conditions, but can be expected to fall within the 1–2 min range and in some cases as long as 10 min (Verreck et al. 2006; Kumar et al. 2008). In order to reduce the residence time in a hot-melt extruder, the level of mixing can often be adjusted by the addition or removal of mixing elements. While reducing the number of mixing elements will, in most cases, decrease residence time, specific shear input is reduced and drug substances may not fully transition to the amorphous state.

13.2.1 *KinetiSol® Dispersing*

KSD is a novel fusion-based processing technique for the rapid production of polymeric amorphous solid dispersions. In this high-energy mixing process, a shaft with protruding blades rotates at speeds of up to 3,500 rpm within a sealed processing chamber containing a pre-blended composition. A cross-sectional view of the processing chamber is illustrated in Fig. 13.1.

Through a combination of kinetic and thermal energy, compositions are processed into a molten mass without the need for external heat input (DiNunzio et al. 2010c). A computer-control module monitors the real-time temperature of the composition and upon reaching the desired endpoint, ejection of the molten material occurs. While laboratory-scale units are operated in batch mode, production scale units are operated as semi-batch processes capable of throughputs as high as 1,000 kg/h.

In a study conducted by DiNunzio et al., solid dispersions were prepared by both KSD- and HME-processing techniques and subsequently characterized (DiNunzio et al. 2010c). The authors demonstrated that amorphous solid dispersions of

Fig. 13.2 In-process temperature profile of ITZ/HPMC E5 solid dispersion produced by KSD processing using a five-point smoothing algorithm (DiNunzio et al. 2010c)

Fig. 13.3 Total and reversing heat profiles of solid dispersions (DiNunzio et al. 2010c)

itraconazole (ITZ) in hypromellose E5 (HPMC) matrices could be successfully prepared by KSD in <15 s with temperatures exceeding 100°C for less than 6 s, as shown in Fig. 13.2.

The absence of crystalline ITZ was confirmed by X-ray powder diffraction (XRPD). Similarly, a differential scanning calorimetry (DSC) analysis demonstrated the absence of crystalline ITZ in HME and KSD compositions, as shown in Fig. 13.3. Further inspection of the reversing heat-flow thermograms demonstrates that dispersions prepared by HME exhibited two distinct glass transition temperatures while those prepared by KSD exhibited a single glass transition temperature, indicating improved homogeneity due to intensive mixing.

As a result of improved homogeneity, the researchers found that compositions processed by KSD exhibited faster *in vitro* dissolution rates than HME-processed solid dispersions. Subsequent *in vivo* rat studies demonstrated that ITZ plasma levels were significantly enhanced over crystalline ITZ. However, ITZ plasma levels were not statistically different from those of the HME-processed composition or the marketed product, Sporanox®.

In a related study, DiNunzio et al. evaluated the utility of the KSD process for the preparation of amorphous solid dispersions with concentration-enhancing polymers (DiNunzio et al. 2010d). Polymers such as these can provide reduced precipitation rates of poorly water-soluble compounds through physical and chemical interactions. The researchers demonstrated that the KSD process was viable for the preparation of compositions containing ITZ, hypromellose acetate succinate (HPMCAS), and Carbomer (C974). All compositions exhibited a single glass transition temperature and the absence of an ITZ melting endotherm indicating that a single-phase system was formed. The absence of crystalline itraconazole was confirmed by XRPD analysis. *In vivo* rat studies demonstrated improved oral bioavailability over previously studied hydrophilic solid dispersions and Sporanox® pellets. However, the pH-dependent solubility of HPMCAS caused high levels of variability in the study.

As previously described, the use of plasticizers in thermal processing can significantly impact the physical stability of an amorphous solid dispersion through increased molecular mobility. It is well established that the molecular motion of an amorphous system is minimized when stored at temperatures of at least 50°C below its glass transition temperature (Hancock et al. 1995; Shamblin et al. 1999; Hancock 2002). Therefore, systems with a glass transition temperature greater than 90°C should be sufficiently stable at room temperature and at temperatures up to 40°C or higher.

The KSD process was recently evaluated for the production of plasticizer-free compositions of Eudragit® L100-55, an enteric polymer with concentration enhancing properties (DiNunzio et al. 2010b). Compositions containing a 1:2 mixture of ITZ:Eudragit® L100-55 could not be effectively processed by HME due to high viscosity and decomposition of the polymer. Triethyl citrate was incorporated into HME compositions at 20% (by dry polymer weight) as a processing aid. Conversely, compositions containing a 1:2 ratio of ITZ:Eudragit® L100-55 were successfully processed by KSD, primarily due to the high torque output inherent to this technology. A titration of the methacrylic acid units demonstrated that the HME and KSD processes did not negatively impact the chemical stability of Eudragit® L100-55. All samples were determined to be amorphous by XRPD. Furthermore, modulated DSC analysis showed that the HME and KSD compositions exhibited glass transition temperatures of 54.2°C and 101.3°C, respectively. Milled samples were placed at accelerated stability conditions (40°C/75% RH) for 6 months to evaluate the physical stability of compositions prepared by each processing method. An XRPD analysis was conducted at 1, 3, and 6 months to assess crystallinity as a measure of physical stability. As shown in Fig. 13.4, crystalline peaks identified as those characteristic of ITZ were found in HME compositions at the 3- and 6-month time points, indicating physical instability due to increased molecular mobility. Compositions prepared by KSD exhibited physical stability over the same 6-month testing period.

Fig. 13.4 XRD patterns of HME and KSD ITZ:Eudragit L100-55 solid dispersions measured over 6 months accelerated stability at 40°C/75% RH. Samples were stored in 30 cc HDPE induction sealed bottles (DiNunzio et al. 2010b)

The ability to process thermally labile compounds by KSD has also been studied recently (DiNunzio et al. 2010a; Hughey et al. 2010). In the study conducted by Hughey et al., a proprietary compound (ROA) that exhibited rapid degradation at acidic pH values and at high temperatures was studied. Compositions containing ROA and Eudragit® L100-55 or HPMCAS-LF, which are characterized as being acidic, were processed by HME and KSD. Results of the HME study showed that rapid degradation of unmiconized ROA occurred in the presence of both polymers, as shown in Table 13.1. Compositions were determined to be crystalline in nature by XRPD analysis. When in its micronized form and at reduced residence times, the extent of ROA degradation decreased and the amorphous character was improved.

The researchers found that the KSD process provided threefold and 1.5-fold drug recovery improvements in Eudragit® L100-55- and HPMCAS-LF-based matrices, respectively, without the need for drug micronization (see Table 13.2). This improvement was attributed to the ability to rapidly process compositions due to high rates of shear. Compositions prepared by KSD were determined to be substantially amorphous. Dissolution rate studies of the solid dispersions demonstrated a two- to threefold improvement in the extent of drug supersaturation when compared to the unprocessed drug substance.

The KSD process has a number of advantages over traditional fusion-based solid dispersion preparation techniques. High shear rates inherent to the KSD process

Table 13.1 Hot-melt extrusion manufacturing conditions and resulting recovery values (Hughey et al. 2010)

| Polymer | Particle size | Temperature (°C) | Screw speed (rpm) | Recirculation time (min) | Recovery (%) | Impurities (%) |
|-------------------|---------------|------------------|-------------------|--------------------------|--------------|----------------|
| Eudragit® L100-55 | Unmicronized | 140 | 300 | 2 | 22.7±0.5 | 55.9 |
| Eudragit® L100-55 | Micronized | 140 | 300 | 0 | 69.1±0.5 | 17.3 |
| HPMCAS | Unmicronized | 170 | 300 | 2 | 70.9±0.3 | 10.2 |

allow for enhanced mixing, reduced processing times, and the formation of plasticizer-free compositions that exhibit excellent physical stability.

13.2.2 Electrostatic Spinning

Electrostatic spinning is a technique that has been used successfully in the polymer industry for many years to produce a variety of products (Doshi and Reneker 1995; Reneker and Chun 1996). As applied in the polymer industry, a polymer in solution is drawn through a capillary tube that is subjected to an electric field. As the electric field intensity is increased, the solution forms a Taylor cone at the tip of the capillary tube. Once the electric field overcomes the force of surface tension, the solution is ejected in the form of an electrically charged jet. As the solvent evaporates, narrow unwoven filaments are formed that have diameters ranging from 50 nm to 5 µm (Doshi and Reneker 1995). An illustration of a simple electrostatic spinning process is shown in Fig. 13.5.

Factors affecting the overall diameter of the electrostatic spun fibers include, but are not limited to, polymer solution viscosity, surface tension of the polymer solution, electric field strength, feed rate, and dielectric constant (Deitzel et al. 2001). This technique was recently applied to the pharmaceutical industry for both controlled and immediate release applications (Ignatious and Baldoni 2001; Kenawy et al. 2002; Verreck et al. 2003b).

In pharmaceutical applications, a drug substance and polymer are dissolved in a solvent system, as would be required in a spray-drying process. In another embodiment, the polymer could be melted in a solvent-free system, provided that the drug substance and polymer are not thermally labile and the resulting viscosity is sufficiently low (Ignatious et al. 2010).

Fig. 13.5 Schematic of electrostatic spinning system (Kenawy et al. 2002)

Fig. 13.6 Scanning electron micrograph of (a) ITZ/HPMC 40:60 w/w electrostatically spun fibers at 16 kV (magnification 2,000 \times), (b) ITZ/HPMC 40:60 w/w electrostatically spun fibers at 24 kV (magnification 500 \times). In the insert (magnification 8,500 \times), the bar represents 3 μm , and (c) ITZ/HPMC 20:80 w/w electrostatically spun fibers at 24 kV (magnification 2,000 \times ; Verreck et al. 2003a)

In one of the first pharmaceutical-related studies, Verreck et al. investigated the use of electrostatic spinning for the preparation of hydrophilic amorphous solid solutions containing ITZ (Verreck et al. 2003a). HPMC-based compositions containing 20% (w/w) and 40% (w/w) ITZ were prepared in an ethanol and methyl chloride co-solvent system. A solids concentration of 12% (w/w) was chosen based on optimal viscosity. A voltage of 16 kV or 24 kV was applied and unwoven fibers were collected. Fibers containing 40% ITZ processed at 16 kV and 24 kV were found to have diameters ranging from 1 to 4 μm and 300 to 500 nm, respectively, as shown in Fig. 13.6a, b. However, as the drug loading was decreased to 20% and processed at 24 kV, fiber diameters ranged from 500 nm to 3 μm , as shown in Fig. 13.6c. These findings demonstrated that drug concentration within the fiber and the electric potential applied can both have a significant impact on the morphology of the resulting fiber.

Unmilled fibers were found to be amorphous in nature and showed no signs of crystalline character, but the presence of a solid solution was not verified. It was found that when milled, the composition containing 40% ITZ exhibited a small degree of crystallinity. An *in vitro* dissolution analysis of the unmilled fibers in 0.1 N HCl showed complete ITZ release; however, the rate was slower than that of solvent cast films and HME-processed compositions.

Data were recently published that further demonstrated the utility of electrostatic spinning for the preparation of solid dispersions (Ignatious et al. 2010). In this work, the researchers evaluated three compounds in poly(ethylene oxide) (POLYOX[®]), vinylpyrrolidone-vinyl acetate copolymer (PVPVA), and poly(vinyl pyrrolidone) (PVP) matrices.

In one example by Ignatious et al., a proprietary compound (Compound I) was electrostatically spun in a PVP matrix at a concentration of 40% and demonstrated by DSC and XRPD analyses to be amorphous. The nanofibers were dosed to fasted adult male beagle dogs to assess their absorption. Similarly, compressed nanofibers (pellets), non-milled compound I, and wet-bead-milled compound I were accessed. The plasma AUC values demonstrated that wet-bead-milled compound I provided the highest degree of absorption, followed by the nanofibers, nanofiber pellets, and non-milled compound I. The researchers stated that the nanofiber composition could be optimized to further improve absorption.

In a second example by Ignatious et al., another proprietary compound (compound II) was formulated by electrostatic spinning in both POLYOX[®] and Eudragit[®] L100-55 matrices. The *in vitro* dissolution rates were studied at pH values of 1.0 and 7.5, as illustrated in Fig. 13.7. At pH 1.0, the matrix utilizing POLYOX[®] exhibited release rates similar to a nano-milled formulation. The dissolution rate of Eudragit[®] L100-55-based matrices was very low due to its poor solubility at this pH value. At a dissolution medium pH of 7.5, the Eudragit[®] L100-55-based electrostatically spun formulation provided a significantly faster dissolution rate than the nano-milled formulation and the POLYOX[®]-based fibers. This dissolution rate increase was primarily due to the amorphous nature of compound II and/or the concentration enhancing properties of Eudragit[®] L100-55.

Similar studies have been conducted on electrostatic spinning technology by other research groups that demonstrate its utility in the preparation of amorphous solid dispersions suitable for oral dosing (Yu et al. 2010a, b). Similarly, this processing method has been utilized to prepare non-biodegradable compositions intended for transdermal use (Verreck et al. 2003b). Yet another interesting application of the technology recently described is the formation of oral fast-dissolving drug-delivery membranes for the delivery of analgesics (Yu et al. 2009a, b).

As discussed, the electrostatic spinning process is capable of providing solid dispersions that exhibit very large surface areas due to the production of nano-sized fibers. The ability of this processing technique to form films with a high surface area makes it an attractive option.

Fig. 13.7 In vitro dissolution profiles of Compound II at (a) pH 1.0 and (b) pH 7.5. From Ignatious et al. (2010)

13.2.3 Ultrasonic-Assisted Compaction

Ultrasonic-assisted compaction is a manufacturing technique that utilizes ultrasonic energy to improve the dissolution characteristics of a drug substance. Specifically, a drug and excipient(s) are compacted in a customized single-station press, as illustrated in Fig. 13.8, and subjected to defined levels of ultrasonic energy and compression forces. Depending on the physicochemical characteristics of the drug substance and

Fig. 13.8 Scheme of ultrasonic apparatus: (a) piezoelectric transducer; (b) booster; (c) upper punch-sonotrode; (d) die; and (e) lower punch (Rodriguez et al. 1998)

excipients, melting can occur. However, temperatures increase rapidly and compositions are not necessarily exposed to high temperatures for extended durations.

This processing technique was first described by Fini et al. (1997) in a preliminary study. The researchers evaluated the utility of ultrasonic-assisted compaction in the preparation of compositions containing indomethacin and β -cyclodextrin. During processing, indomethacin melted and subsequently came into intimate contact with β -cyclodextrin particles. Compositions exposed to ultrasonic frequencies exhibited improved dissolution characteristics over physical mixtures or kneaded compositions, which was attributed to the presence of amorphous indomethacin. Similarly, PVP-based indomethacin systems were prepared (Fini et al. 2002a). Utilizing a PVP matrix allowed for a more rapid dissolution rate than achieved by β -cyclodextrin-based compositions. In a related study, ketoprofen was rendered amorphous and adsorbed onto Eudragit[®] S100, an enteric material with a relatively high glass transition temperature (Sancin et al. 1999). The researchers noted that adsorbed ketoprofen recrystallized at a much lower rate than that of pure ketoprofen.

Fig. 13.9 Scheme of the ultrasonic atomizer (not to scale): (a) ultrasonic generator; (b) booster; (c) sonotrode; (d) inductive coil; (e) supply funnel; and (f) cylindrical chamber (collector) (Rodriguez et al. 1999)

Fini et al. (2002b) studied poly(ethylene glycol) (PEG)-based indomethacin compositions prepared by ultrasonic compaction. It was hypothesized that the ultrasonication compaction process would soften or melt each material based on their low melting points, allowing for mixing within the die cavity to form a solid dispersion. Increasing the ultrasonication energy input resulted in an increased indomethacin dissolution rate. This was attributed to improved mixing and amorphous character in the matrix. However, despite an improvement in dissolution rate, the ultrasonic-assisted compaction process was not able to achieve the dissolution rate of the solid-dispersion control.

The ultrasonication apparatus described above has also been adapted for the preparation of multiparticulate systems, as illustrated in Fig. 13.9 (Rodriguez et al. 1999). In this apparatus, a drug is dispersed in a melted lipid or waxy excipient and dispensed onto a sonotrode. Ultrasonic energy subsequently creates a fine mist of spherically shaped particles that are subsequently cooled and solidified. This manufacturing technique is ideal for compositions containing relatively low viscosity matrices (e.g., lipids and waxes) in which a high surface area is desired.

Cavallari, et al. (2005) evaluated the ability to form Gelucire 50/13-based microparticles containing diclofenac. Resulting microparticles were spherical and

Fig. 13.10 SEM micrographs: (a) ultrasonic-microparticles Diclofenac/Gelucire 10% w/w and (b) details of the surface of a ultrasonic-microparticle Diclofenac/Gelucire 10% w/w (Cavallari et al. 2005)

non-aggregated with a particle size primarily in the range of 150 and 350 μm , as shown in Fig. 13.10. In vitro dissolution analysis demonstrated rapid release kinetics for the ultrasonically prepared microparticles when compared to pure diclofenac or a physical mixture.

While both types of ultrasonic-assisted methods are capable of forming solid dispersions, the spray-congealing technique offers the most promise as it allows for the preparation of high-surface-area solid dispersions of low-viscosity materials. However, it should be noted that a solution of the drug and lipid/wax is formed during the mixing step prior to sonication and the formation of microparticulates. Furthermore, the equipment utilized in the spray-congealing technique is commercially available and is capable of processing up to 5 kg/h (Cavallari et al. 2005).

13.3 Emerging Formulation-Specific Techniques

While the formation of solid dispersions is an effective technique to enhance the bioavailability of poorly water-soluble compounds, there are a variety of other formulation-based techniques that can achieve the same goal. Pharmaceutically acceptable solvents and surfactants have been utilized in liquid-based formulations to improve bioavailability (Yalkowsky 1981). Examples of co-solvent systems used to solubilize drug substances include ethanol, polyethylene glycol, propylene glycol, or glycerol, whereas surfactant systems may include amphoteric compounds such as lecithin, ionic surfactants such as sodium palmitate, or nonionic surfactants such as Cremophor[®] EL and Tween[®] 80 (polysorbate 80) (Gelderblom et al. 2001). Many of the excipients chosen for this purpose exhibit toxicity (Rowe et al. 2009). Cremophor[®] EL and Tween[®] 80 are both examples of nonionic surfactants that are known to elicit unwanted side effects (Alade et al. 1986; Jonkman-De Vries et al. 1996). Specifically, Cremophor[®] EL has been shown to cause severe anaphylactoid hypersensitivity, hyperlipidemia, neurotoxicity, and abnormal lipoprotein patterns

(Gelderblom et al. 2001; Croy and Kwon 2006). Similarly, Tween[®] 80 is a biologically active surfactant and was found to suppress the expected response to low doses of phytohemagglutinin which resulted in E-Ferol being removed from the market (Alade et al. 1986).

In addition to toxicity concerns, compounds solubilized in co-solvents or in micelles formed from low-molecular-weight surfactants are susceptible to precipitation when diluted with physiological fluids. This is particularly true for low-molecular-weight surfactants which traditionally have relatively high critical micelle concentration (CMC) values (Rosen 1989). Liposomes and cyclodextrins have also been utilized as solubilization vehicles or carriers for poorly water-soluble compounds. While these systems generally do not have the same toxicity issues inherent to surfactants, they are limited by low drug loadings within the liposomal membrane and cyclodextrin inner cavity (Torchilin 2007). These disadvantages have created the need for alternative methods of drug solubilization.

13.3.1 *Polymeric Micelles*

Polymeric micelles have emerged as a promising delivery vehicle for poorly water-soluble drug substances and have attracted a significant amount of attention in recent years (Kwon and Kataoka 1995; Jones and Leroux 1999; Torchilin 2001; Gaucher et al. 2005; Aliabadi and Lavasanifar 2006). Amphiphilic di-block or tri-block copolymers consisting of hydrophilic and hydrophobic segments are capable of assembling into micelles through a process that is driven by a reduction in free energy (Gaucher et al. 2005). Once achieving the CMC, specific to the polymer, they orient in aqueous solutions such that the hydrophobic segments form a core in which poorly water-soluble substances can be solubilized (see Fig. 13.11). Hydrophilic sections form a protective shell, known as the corona. These systems may consist of several hundred block copolymers, resulting in a colloidal particle with a diameter ranging from 10 to 100 nm (Kwon and Okano 1996; Rapoport 2007). The resulting micelle shape is dependent on the relative lengths of the hydrophilic and hydrophobic blocks, but is often spherical (Zhang and Eisenberg 1995).

A majority of the amphiphilic block copolymers utilize PEG blocks as the hydrophilic segment with molecular weights ranging from 1 to 15 kDa (Torchilin 2001; Kwon 2003). PEG is particularly well suited to provide steric protection and to prevent recognition by the reticulo-endothelial system (RES) (Moghimi et al. 2001). Furthermore, the use of PEG allows for passive targeting of tumors through the enhanced permeability and retention (EPR) effect due to leaky vasculature. Other hydrophilic segments such as PVP have also been reported for this use and may be more suited for certain applications (Teng et al. 1998; Benahmed et al. 2001; Rapoport 2007).

In contrast to the almost universal use of PEG as the hydrophilic segment in these systems, a much wider range of hydrophobic segments have been reported and may

Fig. 13.11 Micellization model for an amphiphilic AB-diblock copolymer (Adams et al. 2003)

be broadly classified into poloxamers, amino acids, and polyesters (Allen et al. 1999; Adams et al. 2003). Therefore, the physicochemical properties of a block copolymer, including the ability to solubilize specific drugs, are largely dependent on the hydrophobic segment utilized.

The stability of polymeric micelles can be described in both thermodynamic and kinetic terms (Allen et al. 1999). From a thermodynamic standpoint, polymeric micelles are stable provided that the block copolymer concentration is greater than the CMC. When above the CMC, micelles are in dynamic equilibrium with free copolymer molecules, termed unimers. However, the exchange of unimers between polymeric micelles is negligible in certain systems (van Stam et al. 2000; Savi et al. 2006). In comparison to surfactant micelles, polymeric micelles are characterized as having a significantly lower CMC value.

Unlike their surfactant counterparts, polymeric micelles may be kinetically stable for a period of time when diluted to a concentration below that of the CMC (Tian et al. 1993; Kwon and Kataoka 1995; Kwon and Okano 1996). This kinetic stability is a function of the core-forming segment properties (Kwon and Okano 1996; Allen et al. 1999). Provided that the glass transition temperature of the hydrophobic segment is above the physiological temperature, it is expected that the micelle would disassemble more slowly due to the core being in a glassy state (Savi et al. 2006). Conversely, polymeric micelles prepared from block copolymers with a rubbery or liquid-like hydrophobic core (e.g., poloxamers) are more susceptible to disassembly upon dilution (Kwon and Okano 1996).

13.3.1.1 Types and Applications of Polymeric Micelles

As previously discussed, micelles formed from amphiphilic block copolymers provide stable hydrophobic reservoirs capable of solubilizing drug substances. The nature of the block copolymer can have a significant impact on the size of the micelle, the ability to solubilize a specific drug substance, and the rate of drug release. Primarily utilized in intravenous applications, micelles may circulate for extended periods of time with low rates of drug release.

Poloxamers, sold under the trade name Pluronic®, are tri-block copolymers based on poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide)

(PEO–PPO–PEO) and have been researched extensively for their ability to solubilize drug substances (Kabanov et al. 2002). Physicochemical properties of poloxamers such as the CMC and partition coefficients for hydrophobic substances vary widely depending on the relative lengths of the PEO and PPO blocks (Kozlov et al. 2000). Due to the low glass transition temperature of the hydrophobic segments, poloxamer micelles do not exhibit a high degree of kinetic stability (Kwon and Okano 1996). In a comprehensive study conducted by Batrakova et al., epirubicin and doxorubicin were solubilized by micelles formed from three different poloxamer types: Pluronic® L61, P85, and F108 (Batrakova et al. 1996). These authors determined that anti-tumor activity was dependent on the concentration of the poloxamer and its hydrophobicity. It has also been reported that poloxamers above and below the CMC can facilitate the delivery of drug substances across the blood-brain barrier (Batrakova et al. 1999).

Amino acid-based hydrophobic segments in block copolymers often contain functional groups that allow for derivations to be prepared (Adams et al. 2003). This allows copolymers to be customized for specific drug substances and also allows for the formation of drug–polymer conjugates. In a recent study, paclitaxel was incorporated into a poly(ethylene glycol)–*b*-poly(aspartate)-based copolymer modified with 4-phenyl-1-butanolate to improve solubilization (Hamaguchi et al. 2005). Upon intravenous administration to mice, it was found that the micellar formulation provided a 90-fold increase in the plasma area under the curve (AUC) over free paclitaxel. Similarly, tumor AUC values were approximately 25-fold higher than that of free paclitaxel. In another study conducted by Lavasanifar et al., a poly(ethylene oxide)–*b*-poly(L-amino acid) copolymer was modified with aliphatic side chains to form poly(ethylene oxide)–*b*-poly(*N*-hexyl stearate L-aspartamide) (Lavasaniifar et al. 2001). This copolymer was found to self-assemble and effectively solubilize amphotericin B, resulting in reduced hemolytic activity when compared to free amphotericin B.

Block copolymers containing poly(ester) hydrophobic blocks such as poly(D,L-lactic acid) (PLA) or poly(lactic-co-glycolic acid) (PLGA) have also been studied as drug carriers (Yasugi et al. 1999; Kataoka et al. 2001; Lin et al. 2003). Much like copolymers prepared from amino acid-based block copolymers, ester-based copolymers can be derivatized to modulate drug-release rates or to increase drug loadings. The modification of PLA to form poly(mono hexyl-substituted lactide) (PmHLA) was recently reported (Trimaille et al. 2007). The resulting hydrophobic PmHLA block exhibited glass transition temperatures significantly lower than that of PLA and subsequently exhibited faster release rates of tetracycline. In a separate study, Trimaille et al. polymerized PmHLA and poly(di-hexyl-substituted lactide) (PdHLA) hydrophobic blocks with methoxy-poly(ethylene glycol) (mPEG) to form amphiphilic block copolymers (Trimaille et al. 2006). They found that mPEG-PmHLA- and mPEG-PdHLA-based micelles were capable of significantly higher griseofulvin loadings and encapsulation efficiencies than mPEG-PLA block copolymers. This improvement was attributed to the increased hydrophobicity of the micelle core.

13.3.1.2 Recent Advances in the Use of Polymeric Micelles

While a significant amount of research has been conducted on the ability of polymeric micelles to improve the bioavailability of poorly water-soluble drug substances, the focus has primarily been on intravenous delivery. Oral delivery of polymeric micelles has become an area of interest for many researchers as it allows for improved stability and self-medication.

The stability of cyclosporin-A-loaded mPEG-PdHLA micelles was recently studied (Mondon et al. 2011). While these systems provided a 500-fold improvement in the water solubility of cyclosporin A, significant drug loss was observed when stored at 25°C and 37°C. In order to improve the long-term stability of micelles formed from mPEG-PHLA block copolymers, Di Tommaso et al. (2010) studied the ability to create a solid dosage form containing drug-loaded micelles. The authors prepared micelles containing cyclosporin A and evaluated various lyophilisation stabilizers. They found that 10% sucrose provided adequate protection to the micelles and allowed for a lyophilisate that could be reconstituted to yield transparent micellar solutions of cyclosporin A. Spray drying could potentially be utilized in systems such as these to form powders capable of being formulated in oral dosage forms.

Oral delivery of micellar systems is hindered by relatively low drug loadings within polymeric micelles (Gaucher et al. 2010). Furthermore, durations of drug release from these systems far exceeds the transit time in the gastrointestinal (GI) tract. While it is entirely possible for a nano-sized polymeric micelle to be absorbed for systemic circulation in the GI tract, the hydrophilic corona inherent to these systems limits this to some degree (Behrens et al. 2002).

The maximum drug loading that can be successfully applied to a polymeric micelle is highly dependent compatibility between the drug substance and the core-forming hydrophobic block. In a recent study, novel block copolymers based on hydrotropic agents were synthesized and their ability to solubilize paclitaxel was evaluated and compared to other micellar systems (Huh et al. 2005). Based on its ability to solubilize paclitaxel, poly(2-(4-vinylbenzyloxy)-*N,N*-diethylnicotinamide) (PDENA) was utilized as the hydrophobic block while PEG was utilized as the hydrophilic block. Resulting micellar solutions were lyophilized to achieve a powder capable of being redispersed. A maximum paclitaxel drug loading of 37.4% (w/w) was obtained in PEG-PDENA systems, whereas the highest value obtained in PEG-PLA was 27.6% (w/w). Dissolution analysis of solubilized paclitaxel demonstrated that PEG-PDENA systems with a loading of 31.3% (w/w) exhibited complete release within 24 h, whereas systems at 25.9% loading exhibited complete release after 48 h, as shown in Fig. 13.12.

This trend was attributed to decreased drug-polymer interactions at higher loading values. For comparison, complete paclitaxel release occurred after 72 h in PEG-PLA-based micelles, indicating that increased hydrophobicity of the core inhibited the release of paclitaxel. Lee et al. showed that when lyophilized micelles at a loading of 25.9% (w/w) were redispersed in water, a maximum paclitaxel concentration of 38.9 mg/mL could be obtained (Lee et al. 2006). At this concentration,

Fig. 13.12 Release kinetics from polymer micelles and paclitaxel powders in 0.8 M sodium salicylate solution at 37°C. The total amount of loaded paclitaxel was 0.1 mg (Huh et al. 2005)

the solubility of paclitaxel was increased by a factor of 5,000 over its equilibrium solubility. In vivo rat studies showed that the paclitaxel bioavailability of the PEG-PDENA-based system was 12.4%, a considerable improvement over the reported 6.5% bioavailability of the marketed Taxol® formulation (Peltier et al. 2006).

In an effort to increase the drug-release rate from polymeric micelle systems, block copolymers with ionizable groups have been studied (Sant et al. 2004; Satturwar et al. 2007; Kim et al. 2008). In these systems, a drug substance is solubilized in a hydrophobic core modified with pH-sensitive moieties. When administered orally, systems such as these pass through the stomach without releasing the drug substance. At pH values inherent to the upper intestines, the pH-sensitive moiety in the hydrophobic core begins to ionize and the drug is subsequently released. In a recent study, PEG-*b*-PDENA copolymers were modified with acrylic acid (AA), a pH sensitive moiety, at levels ranging from 0 to 50 mol% (Kim et al. 2008). With AA addition levels as low as 20 mol%, dissolution rates of paclitaxel were increased by a significant amount (<12 h). In another example, novel copolymers composed of PEG-*b*-poly(alkyl acrylate-*co*-methacrylic acid) (PEG-*b*-P(AIA-*co*-MAA)) were evaluated as pH-sensitive polymeric micelles for the delivery of progesterone (Sant et al. 2004). In vitro dissolution studies demonstrated that as the pH was increased from pH 1.2 to 7.2, progesterone dissolution rates increased and exhibited complete release within 6 hours. In a related study, the oral bioavailability of fenofibrate from pH-dependent PEG-*b*-P(AIA-*co*-MAA) micelles was evaluated in rats (Sant et al. 2005). The prepared systems exhibited an oral bioavailability improvement of 156% relative to a fenofibrate coarse solution and a 15% improvement over the marketed product, Lipidil Micro®.

In another approach to ensure complete drug release within the GI tract, block copolymers with bioadhesive moieties are being investigated to prolong their transit time (Bromberg 2008). The utility of poloxamer unimers modified with

poly(acrylic acid) (PAA), a bioadhesive component, to improve the oral bioavailability of megestrol acetate in rats was studied (Alakhov et al. 2004). A significant improvement in oral bioavailability was reported over the control formulation. The time required to reach the C_{\max} for the poloxamer-PAA-based formulation was threefold longer than that of the unmodified formulation, indicating that the addition of PAA to the block copolymer provided increased residence times. In another study, researchers demonstrated that poloxamer-PAA-based micelles provided a 10-fold enhancement in the oral bioavailability of paclitaxel in mice over the intravenous route when co-administered with cyclosporin A (Bromberg 2008).

Polymeric micelles provide a number of advantages over low-molecular-weight surfactants for the delivery of drug substances. These include reduced toxicity, a significantly lower CMC, and the ability to be prepared in solid form due to their high kinetic stability.

13.3.2 Mesoporous Silica

Ordered mesoporous silica (OMS) has recently emerged as a substrate with properties ideal for the delivery of poorly water-soluble compounds. This silica material is characterized as having a hexagonal array of uniform cylindrical mesopores, each separated by a thin wall, exhibiting a very high surface area (Beck et al. 1992). Figure 13.13 demonstrates the morphology typical of OMS.

Scaffolds are available in a wide range of mesopore diameters ($2 \text{ nm} < D_p < 50 \text{ nm}$) and thus have relatively large volumes with controllable size (Vallet-Regí 2006). Two of the specific types of OMS investigated in recent years are MCM-41 (Mobil Composition of Matter No. 41) and SBA-15 (Santa Barbara Amorphous No. 15) (Mellaerts et al. 2008b). The pore diameter ranges between 2 and 6 nm for MCM-41 and 4 and 13 nm for SBA-15. Furthermore, SBA-15 is characterized as having micropores with diameters less than 2 nm along its cylindrical walls (Kruk et al. 2000). While MCM-41 and SBA-15 mesoporous silica types do not exhibit

Fig. 13.13 SEM (*left*) and TEM (*right*) image of OMS. Scale bars correspond to 1 μm and 100 nm, respectively (Mellaerts et al. 2008b)

Fig. 13.14 Enhanced release of itraconazole from SBA-15 resulting from the rapid influx and competitive adsorption of water (Mellaerts et al. 2007)

interconnecting mesopores, Heikkilä et al. (2007) recently described a novel silica material with a foam-like three-dimensional structure, TUD-1, which is characterized as having interconnecting pores. The pore diameter of TUD-1 ranges from 2.5 to 20 nm, significantly broader than that of MCM-41 or SBA-15 OSM. The use of functionalized porous silicon (PSi) has also been reported as a high-surface-area carrier with pore sizes ranging between 2 and 30 nm (Salonen et al. 2002).

When utilized as a delivery system, drugs are loaded into empty mesopores of the silica matrix. Upon exposure to an aqueous medium, hydrophobic drugs are released, as shown in Fig. 13.14. The desorption of drugs in the presence of water is explained by the affinity OMS has for water over hydrophobic compounds and is diffusion controlled (Andersson et al. 2004; Mellaerts et al. 2008a).

Vallet-Regi, et al. (2001) first evaluated OMS as a reservoir for controlled drug-delivery systems. In this initial study, the researchers utilized MCM-41 with two different pore sizes for the delivery of ibuprofen, whose molecular size was in the range of the mesopores. In order to load the OMS, substrates were submerged in a solution of ibuprofen and hexane (33 mg/mL). Upon removal, substrates contained 30% (w/w) ibuprofen, demonstrating that ibuprofen was absorbed into the mesopores which was further confirmed by BET analysis. *In vitro* dissolution analysis of the ibuprofen-loaded OMS demonstrated that complete drug release occurred after 3 days.

With a high concentration of silanol groups on the mesoporous silica wall surfaces, functionalization with many types of organic molecules to modulate drug-release kinetics is possible (Ukmar and Planinšek 2010). Researchers have reported the use of a variety of functional moieties for this purpose, including those that allow pH-dependent release (Muñoz et al. 2002; Song et al. 2005; Yang et al. 2005; Qu et al. 2006; Tang et al. 2006; Bernardos et al. 2008; Xu et al. 2008; Wang et al. 2009; Tang et al. 2010). The functionalization of PSi by thermal carbonization and thermal oxidation was reported to create surfaces acceptable for drug-delivery applications (Salonen et al. 2005).

Fig. 13.15 Release profiles from SBA-15_{7.9} with different loadings of itraconazole (wt%) and comparison with dissolution of crystalline itraconazole (Mellaerts et al. 2007)

13.3.2.1 Recent Advances in the Use of Mesoporous Silica

While the focus of initial studies conducted by Vallet-Regi et al. was on controlled drug-delivery systems, a major focus of OSM research has shifted to immediate release systems for the delivery of poorly water-soluble compounds. Recently, Mellaerts et al. studied the ability to formulate ITZ in SBA-15 OMS (Mellaerts et al. 2007). In this study, pore sizes ranging from 4.5 to 9.0 nm and drug loadings up to 31.2% (w/w) were investigated. ITZ was loaded into the OMS material by utilizing a solution of ITZ in methylene chloride. The physical state of ITZ within the OMS was characterized by DSC which demonstrated that ITZ was molecularly dispersed at concentrations below 26.8% (w/w). Dissolution analysis of various ITZ loadings in SBA-15 demonstrated rapid release at all concentrations, as shown in Fig. 13.15. At an itraconazole concentration of 37.5% (w/w), the presence of crystalline ITZ inhibited its dissolution rate.

A study was conducted to evaluate the effect of mesopore size on the dissolution rate of ITZ at 10% loading. As shown in Fig. 13.16, the dissolution rate increased drastically as the mesopore size was increased from 4.5 to 6.4 nm while a further increase to 7.9 nm and 9.0 nm resulted in minor improvements. This demonstrated that pores measuring 4.5 nm acted as a diffusional barrier to molecular ITZ.

Four of the most common types of mesoporous materials (MCM-41, SBA-15, TUD-1, and carbonized PSi) were recently evaluated for their ability to carry and deliver ibuprofen (Heikkilä et al. 2007). Of the four types tested utilizing the solvent-loading method, SBA-15 provided the highest drug load at over 50% (w/w), primarily due to its high pore volume. The researchers hypothesized that the loading

Fig. 13.16 Release profiles of itraconazole from SBA-15 materials with different pore sizes (nm). Each release experiment was performed in triplicate (Mellaerts et al. 2007)

of MCM-41 was lower than expected due to clogging, since mesopore diameters were only a few times larger than an individual ibuprofen molecule. Dissolution studies showed that each system allowed for rapid release of ibuprofen in all mediums studied. However, the TUD-1-based carrier provided the most rapid dissolution rate due to its interconnecting pores. MCM-41-based compositions exhibited the slowest dissolution rate. This result was attributed to its small pores acting as diffusional barriers, as previously discussed.

Recently, the loading method of drug into OMS (SBA-15) was investigated for ibuprofen and ITZ (Mellaerts et al. 2008a). The researchers evaluated the location of drug particles within the OMS after utilizing: adsorption from organic solution, incipient wetness impregnation, and melting the drug in the presence of OMS. The organization of drug molecules within the mesopores utilizing each of the adsorption methods is illustrated in Fig. 13.17. The researchers found that incipient wetness impregnation was the most effective method to ensure an even distribution of ITZ along the cylindrical walls and inside the micropores. When adsorbing ITZ from a dilute solution, the researchers found that ITZ was inside the mesopores. However, higher concentrations were found at the mesopore openings. When the melting method was utilized, glassy ITZ was deposited on the outside of the SBA-15 particles, primarily due to its high viscosity. Conversely, ibuprofen was successfully loaded into SBA-15 OMS by each of the three adsorption methods. This finding can be attributed to the relatively small size of ibuprofen in comparison to ITZ.

The oral bioavailability of ITZ adsorbed onto OMS was recently evaluated in rabbits and dogs by Mellaerts et al. (2008b). Results of the study demonstrated that

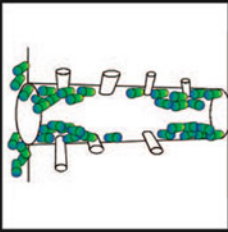

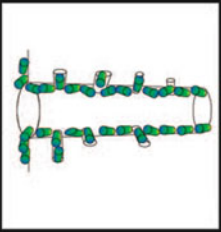

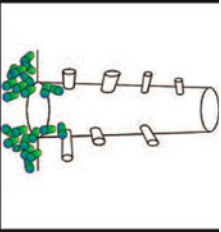

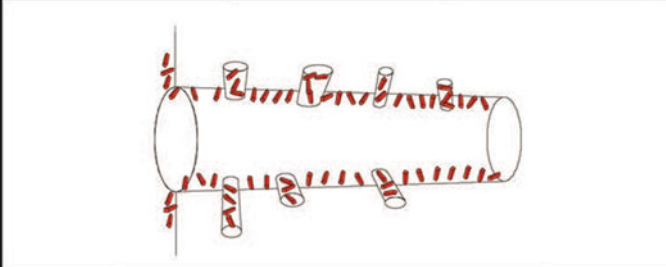

| | Solvent | Incipient wetness | Melt |
|--------------|--|---|--|
| Itraconazole |  |  |  |
| Ibuprofen |  | | |

Fig. 13.17 Physical state of itraconazole and ibuprofen upon association with SBA-15 loaded according to the solvent method, incipient wetness method, and melt method (Mellaerts et al. 2008a)

the oral absorption of OMS-based formulations of ITZ exhibited plasma AUC values similar to those of Sporanox[®], the marketed drug product. This effectively demonstrated that OSM can increase the oral bioavailability of poorly water-soluble drug substances.

OMS offers the ability to formulate high levels of poorly water-soluble drug substances in an amorphous form. Being a relatively new technique, its feasibility for this purpose has not been fully characterized.

13.4 Summary

A number of techniques have emerged in recent years that have applications in the formulation of poorly water-soluble compounds. However, selection of a suitable formulation or processing technique is highly dependent on the specific physico-chemical properties of the drug substance being studied. Many drug substances exhibit instabilities or other properties that severely limit the number of feasible formulation and processing techniques. The emerging technologies described in this chapter offer specific advantages over traditional formulation and processing techniques which may allow certain drugs to be formulated that would otherwise not be possible.

Method Capsule 1

Preparation of Solid Dispersions: KinetiSol® Dispersing

Based on the method reported by DiNunzio et al. (2010b)

Objective

- To rapidly prepare plasticizer-free solid dispersions containing Eudragit® L100-55

Equipment and Reagents

- Eudragit® L100-55
- Itraconazole
- Liquid nitrogen
- KinetiSol® Dispersing Compounder
- Impact mill
- 60-mesh screen

Method

- Input an ejection temperature of 158 °C and a rotational speed of 3,000 rpm into the control module.
- Mix a 1:2 blend of itraconazole:Eudragit® L100-55 in a polyethylene bag for 1-min.
- Charge the blended material into the processing chamber.
- Pre-cool steel plates with liquid nitrogen.
- Start the compounding process.
- Using the data-acquisition system, monitor temperature and rotational speeds.
- After material is discharged, quench between chilled plates.
- Grind the brittle material in an impact mill and pass through a 60-mesh screen.

Results

- The temperature of the blend reached 158°C in 14.1 s with exposure to temperatures greater than 100°C for only 2 s, resulting in no chemical degradation of Eudragit® L100-55.
- X-ray powder diffraction patterns indicated that the composition was amorphous.
- Differential scanning calorimetry thermograms showed the presence of a single-phase system with no endothermic events.
- The plasticizer-free composition exhibited a high degree of physical stability due to its high glass transition temperature.

Method Capsule 2

Preparation of Solid Dispersions: Electrostatic Spinning

Based on the method reported by Verreck et al. (2003a)

Objective

- To prepare solid dispersions of itraconazole by electrostatic spinning

Equipment and Reagents

- Hypromellose
- Itraconazole
- Ethanol
- Methylene chloride
- Electrostatic spinner
- Turbula mixer
- Cryogenic mill
- Liquid nitrogen

Method

- Prepare physical blends containing 20% w/w or 40% w/w itraconazole by mixing in a Turbula mixer for 10 min
- Prepare a 12% w/w solution of the itraconazole: hypromellose blend in a mixture of ethanol and methylene chloride (40:60 ethanol:methylene chloride w/w)
- Place the solution into the spinneret and apply a high voltage (16–24 kV)
- *Optional:* Mill the resulting fibers by cryogenic grinding

Results

- SEM analysis demonstrated that drug concentration and processing voltage can significantly impact fiber size and shape.
- Differential scanning calorimetry thermograms showed that compositions containing 20% (w/w) and 40% (w/w) itraconazole were amorphous.
- Differential scanning calorimetry thermograms indicated that the milling process facilitated recrystallization of amorphous itraconazole.
- Dissolution rates of itraconazole were found to be highly dependent on the drug:polymer ratio, fiber diameter, and presentation used (nonwoven fabrics, milling, etc.).

Method Capsule 3

Preparation of Solid Dispersions: Ultrasonic-Assisted Compaction

Based on the method reported by Fini et al. (2002b)

Objective

- To prepare dispersions of indomethacin by ultrasonic-assisted compaction

Equipment and Reagents

- Indomethacin
- Polyethylene glycol 4000, 5500, or 6000
- Magnesium stearate
- Talc
- Ultrasonic-assisted tableting machine
- Turbula mixer

Method

- Mix composition containing 10% indomethacin, 88% polyethylene glycol (4000–6000), 1% magnesium stearate, and 1% talc (w/w) in a Turbula mixer for 15 min.
- Transfer 1 g of the blend to the ultrasonic-assisted tableting machine equipped with a 25-mm punch.
- Subject the blend to a frequency of 25 kHz, allowing the polyethylene glycol to become molten.
- Mill the solidified wafer and sieve such that a particle size range of 75–150 μm is obtained.

Results

- Differential scanning calorimetry thermograms did not exhibit an endothermic peak associated with indomethacin.
- X-ray diffractograms of the sonicated composition showed significantly decreased crystallinity in comparison to material that was not sonicated.
- The dissolution rate of indomethacin was significantly enhanced by ultrasonic compaction.
- Dissolution rates of indomethacin were found to be highly dependent on energy input with higher levels approaching that of a true solid dispersion.

Method Capsule 4

Preparation of Solid Dispersions: Ultrasonic-Assisted Congealing

Based on the method reported by Cavallari et al. (2005)

Objective

- To prepare multiparticulate dispersions of diclofenac by ultrasonic-assisted compaction

Equipment and Reagents

- Diclofenac
- Gelucire 50/13
- Ultrasonic-assisted congealing apparatus
- Heat source

Method

- Heat Gelucire 50/13 to 10°C above its melting point.
- Add diclofenac (10% w/w) to the Gelucire 50/13 and stir to complete dissolution.
- Transfer the molten mixture to the thermostated reservoir preset to 60°C.
- Atomize the molten mass into small droplets by bringing the mass into contact with the sonotrode.
- Allow the atomized small droplets to fall freely and solidify at room temperature.
- Collect the microparticles and store in a vacuum desiccator at room temperature.

Results

- Scanning electron microscopy showed that microparticles were spherical or elliptical in shape and nonaggregated.
- Sieve analysis demonstrated that the predominant size range was 150–350 μm .
- Differential scanning calorimetry thermograms did not exhibit an endothermic peak associated with diclofenac at loadings up to 20% (w/w).
- X-ray diffraction diffractograms exhibited a small degree of crystallinity that can be attributed to diclofenac, indicating that the microparticles were not completely amorphous.
- Dissolution rates of diclofenac from microparticles were significantly enhanced in comparison to that of the physical mixture.

Method Capsule 5

Preparation of Solid Dispersions: Polymeric Micelles

Based on the method reported by Lee et al. (2006)

Objective

- To prepare polymeric micelles containing paclitaxel suitable for oral administration

Equipment and Reagents

- Paclitaxel
- PEG-b-P(VBODENA) copolymer
- Acetonitrile, DMF, or DMAc
- Dialysis membrane with 1,000-Da molecular weight cutoff

Method

- Dissolve 10 mg of block copolymer in 2 mL of acetonitrile, DMF, or DMAc
- Add paclitaxel to the block copolymer solution at paclitaxel:copolymer ratios ranging from 0.25:1 to 0.6:1
- Stir the solution for 6 hours at room temperature
- Dialyze using a membrane against 6 L of distilled water for 24 h
- Filter through 0.45 μm membrane filters
- Lyophilize the filtered material containing micelles

Results

- Loading analysis demonstrated that paclitaxel loading capacity was enhanced with increasing block length of P(VBODENA).
- Lyophilized micelles could be dissolved in water to achieve a concentration that is five orders of magnitude greater than that of paclitaxel in water.
- Differential scanning calorimetry thermograms of lyophilized micelles did not exhibit an endothermic event related to paclitaxel, indicating a molecular dispersion.
- Dynamic light-scattering experiments showed that micelles were between about 105 and 120 nm which was maintained in solution for more than 4 weeks.
- Cytotoxicity analysis demonstrated that paclitaxel micelles were as much as two orders of magnitude more effective than controls.
- Bioavailability of paclitaxel was determined to be approximately twofold higher than that of the marketed formulation, Taxol®.

Method Capsule 6

Preparation of Solid Dispersions: Mesoporous Silica

Based on the method reported by Mellaerts et al. (2008b)

Objective

- To prepare mesoporous silica loaded with itraconazole

Equipment and Reagents

- Itraconazole
- Ordered mesoporous silica (OMS)
- Methylene chloride
- Rotary mixer

Method

- Prepare a 5 mg/mL solution of itraconazole in methylene chloride.
- Add OMS at a OMS:Itraconazole ratio of 75:25 and agitate for 24 h with a rotary mixer.
- Remove methylene chloride by evaporation and dry powder overnight at 35°C.
- Heat mixture to 100°C for 5 min under vacuum and at 40°C for 48 h to ensure complete removal of methylene chloride.

Results

- Differential scanning calorimetry thermograms did not exhibit glass transition or endothermic events, indicating that itraconazole was molecularly dispersed within the OMS.
- BET analysis showed that the surface area of OMS decreased from 844 to 355 m²/g after loading with itraconazole.
- Dissolution studies demonstrated that release rates of itraconazole from OMS were significantly faster than crystalline itraconazole.
- Bioavailability of itraconazole-loaded OMS was found to be similar to that of the marketed product, Sporanox®.

Chapter 14

Scientific and Regulatory Considerations for Development and Commercialization of Poorly Water-Soluble Drugs*

Zedong Dong and Hasmukh Patel

Abstract This chapter focuses on the Chemistry, Manufacturing, and Controls (CMC) from the scientific and regulatory perspective of the development of poorly water-soluble drugs to provide insights into regulatory filing from Investigational New Drug Application (IND) to New Drug Application (NDA) submission. The chapter includes two primary sections to cover the two regulatory stages for CMC module of filing, IND and NDA. The IND section of the chapter includes the following contents: (1) brief description of general filing requirements as outlined in the Code of Federal Regulations (CFR) and relevant guidances; (2) discussion of potential regulatory issues for developing poorly water-soluble drugs using various pharmaceutical technologies in the IND stage, i.e., solid-form selection, particle-size reduction, lipid formulation, and amorphous solid dispersion. The NDA section of the chapter includes the following: (1) general regulatory filing requirements of an NDA application; (2) potential regulatory issues associated with poorly water-soluble drugs; detailed discussions are carried out on topics including solid-form selection of the drug substance, drug product development using novel pharmaceutical technologies, development of control strategies, etc.; (3) case studies of marketed drug products of poorly water-soluble drugs in various dosage forms; this part uses the public information of the approved products as examples to support the discussions as outlined in part (2); and (4) brief discussion on the concept of Biopharmaceutics Classification System (BCS) in the development of poorly soluble drugs. The book chapter concludes with a brief summary which emphasizes on the link between regulation and science.

*This book chapter was written by Zedong Dong and Hasmukh Patel in their private capacity. No official support or endorsement by the Food and Drug Administration is intended or should be inferred.

14.1 Introduction

The drug-development process is a multidisciplinary effort, from therapeutic target identification and validation (Lowe et al. 2009), lead series selection and structural optimization, preformulation characterization (Borchardt et al. 2004) and formulation development, nonclinical safety assessment, to the demonstration of safety and efficacy in clinical trials, and eventual submission of a New Drug Application (NDA), and final approval for marketing upon review by the agency (Guarino 2004; Rogge and Taft 2010). Similarly, regulation of drug development and approval involves expertise from many areas (chemistry, medicine, toxicology, clinical pharmacology, statistics, etc.) to assure the safety and rights of the subjects in all phases of an Investigational New Drug Application (IND), to help assure adequate quality of the scientific evaluation of drugs to permit an evaluation of the drug's safety and efficacy in Phases 2 and 3 clinical studies, and to ensure both the safety and efficacy of a commercial drug product in the patients upon approval of an NDA (FDA 2010; 21 CFR 312.22(a)).

With the advancement of science and technology, a large number of new chemical compounds are generated in the discovery stage. Through modern screening technologies, including *in silico* and/or high-throughput screening, the pharmacophore for the therapeutic target is identified (Florence 2009; Hou and Xu 2004; Yang 2010). With further *in vitro* screening/characterization in late discovery/early development stage, if satisfactory preliminary reading on the safety and efficacy of the lead(s) is obtained from preclinical testing in animals, the lead compound(s) is moved forward into clinical development (Salyers 2009; Rogge and Taft 2010). It is estimated that 40–60% of these new chemical compounds pose technical challenges to the formulation scientists due to poor aqueous solubility (Dubin 2006; Lipinski 2000; Merisko-Liversidge and Liversidge 2008). From literature, it appears that the majority of new small molecule compounds that go into clinical trials have low aqueous solubility, particularly in the therapeutic area of oncology. With the challenging solubility hurdle for this type of compounds, their development into a potential drug candidate will be limited due to severely compromised bioavailability, unless appropriate pharmaceutical technologies, such as those discussed in the previous chapters of this book, are utilized. With this background information, this chapter focuses on the scientific and regulatory considerations for developing and commercializing small molecule poorly water-soluble small molecule drugs for oral administration from the perspective of Chemistry, Manufacturing, and Controls (CMC).

14.2 Investigational New Drug Application (IND) stage

With adequate preclinical characterization of and data generation for a new chemical compound on its physicochemical properties, drug metabolism and pharmacokinetics (DMPK), toxicology, and demonstration of efficacy in animal models, a

sponsor may decide to bring the compound to further testing in human subjects through an IND. IND submission and maintenance are regulated by 21 CFR Part 312. Specifically, the subparts that are related to the CMC portion of an IND submission are 21 CFR 312.23(a)(7), 312.31, and 312.33. According to the regulation, for each phase of the investigation, the sponsor is required to submit sufficient information to assure the proper identification, quality, purity, and strength of the investigational drug. However, with the progress of the investigation, and with more knowledge and experience gained, new CMC information is required to be submitted in amendments with updates on drug substance and drug product to support ongoing clinical studies as well as future NDA submission.

14.2.1 Initial IND Submission for Phase 1 Clinical Study

Per regulations, the initial phase 1 CMC submission generally emphasizes on the identification and control of the raw materials, the new drug substance,¹ and the investigational new drug product² to ensure the safety of the subjects in the proposed clinical studies. The following is a brief summary of the documentation needed for submission. For detailed information, please refer to the relevant FDA guidance (FDA 1995).

Before entering into a phase 1 clinical study, as per 21 CFR 312.23(a)(7)(iv)(a), the following information for the new drug substance is required to be submitted to the agency for evaluation (FDA 1995): (1) “a description of the drug substance, including its physical, chemical, or biological characteristics.” This includes the physicochemical properties and preliminary characterization for the elucidation of the molecular structure. (2) “the name and address of its manufacturer.” The sponsor should provide the street address of the manufacturer of the drug substance for phase 1 clinical trial. (3) “the general method of preparation of the drug substance.” The sponsor should provide a brief description of the manufacturing process. A detailed flowchart is also recommended. (4) “the acceptance limits and analytical methods used to assure the identity, strength, quality, and purity of the drug substance.” A set of scientifically acceptable specifications (tests, acceptance criteria, and analytical procedures) should be provided. There is no need to submit any validation data at this stage of investigation. (5) “information sufficient to support stability of the drug substance during the toxicological studies and the planned clinical studies.” Preliminary stability data to support the proposed clinical study(ies), along

¹ Drug substance means an active ingredient that is intended to furnish pharmacological activity or other direct effect in the diagnosis, cure, mitigation, treatment, or prevention of disease or to affect the structure or any function of the human body, but does not include intermediates use in the synthesis of such ingredient (21 CFR 314.3(b)).

² Drug product means a finished dosage form, for example, tablet, capsule, or solution, that contains a drug substance, generally, but not necessarily, in association with one or more other ingredients (21 CFR 314.3(b)).

with the tests, acceptance criteria and the analytical methods, should be provided for review.

According to 21 CFR 312.23(a)(7)(iv)(b), the following information for the investigational drug product is required before a phase 1 study begins: (1) “a list of all components (active³ and inactive), which may include reasonable alternatives for inactive compounds, used in the manufacture of the investigational drug product, including both those components intended to appear in the drug product and those which may not appear but which are used in the manufacturing process.” Information on the quality of the inactive ingredients such as compendial grade (USP), GRAS (i.e., Generally Regarded As Safe as per 21 CFR 170–199) should be provided. For those excipients (e.g., novel excipients) that are noncompendial or not included in the GRAS list, additional information may be needed to demonstrate their safety. (2) “where applicable, the quantitative composition of the investigational new drug product, including any reasonable variations that may be expected during the investigational stage.” A brief summary of the composition of the investigational new drug product should be submitted. (3) “the name and address of the drug product manufacturer.” (4) “a brief, general description of the method of manufacturing and packaging procedures as appropriate for the product.” Usually, a manufacturing flow diagram is submitted together with the brief description of the manufacturing process. (5) “the acceptable limits and analytical methods used to assure the identity, strength, quality, and purity of the drug product.” A brief description of the acceptance limits and their justifications, and the scientifically sound analytical methods should be submitted. Method validation data are not needed at this early stage of the investigation. (6) “and information sufficient to assure product’s stability during the planned clinical studies.” The sponsor should provide a brief description of the stability study and stability specifications (tests, acceptance criteria, and analytical procedures). Preliminary stability data of a representative batch in the proposed container closure should be provided (FDA 1995).

At phase I stage, preliminary information on the physicochemical properties of a drug substance is usually available, such as pKa, logP, solubility in various solvents, pH-solubility profile, solution stability, early reading of solid state stability, etc. Depending on the development strategies among different sponsors, certain information may not be available at this stage of development, such as polymorphism/solid-form selection, or drug–excipient compatibility for supporting formulation development. In the case of poorly water-soluble compounds, based on the characterization data (chemistry and nonclinical studies) from early development, a number of approaches may be tested during formulation development for phase I studies, but the most commonly used approaches are solid-form selection, particle-size reduction, lipid formulation, solubilization using cosolvent, or higher energy form (e.g., solid dispersion) of the drug substance with the final dosage forms usually suspension, tablet, or capsule.

³ Active also refers to drug substance.

In the early stage of clinical trials, from the regulatory perspective, the main focus is to ensure the safety of the subjects. The initial proposed drug substance specifications are usually based on the limited information from the batch analysis results and the stability data of the drug substance used in the pre-clinical toxicology studies for the IND submission. Generally speaking, toxicology thresholds as recommended by ICH Q3A (2006a), Q3B (2006b) are one reasonable approach. Known genotoxic and other noxious impurities may require additional controls. It may be premature to include certain specification items in an initial IND, such as crystalline form, particle size, or surface area, due to limited body of available information. However, if sufficient information and data are already generated, it is desirable to include preliminary acceptance criteria for these items to ensure the quality of the test drug product. Similarly, the proposed specifications for the drug product are usually based on the information from a very limited number of batches of drug product manufactured and any short-term stability study results. Prior knowledge of similar drug products developed may be a useful source of reference. Therefore, at this stage of the investigation, clear establishment of the acceptance criteria for certain specification items may not be realistic due to limited experience and lack of data accumulation for the drug substance and the drug product. The limits or acceptance ranges proposed for these specification items are usually tentative, and some parameters may be monitored simply for the purpose of information collection. In addition, during the development, it is very likely that changes will be made to the drug substance (such as synthetic routes, reagents, organic solvents, reaction conditions, batch size, crystalline form, etc.) or drug product (formulation composition, manufacturing process/equipment, etc.) for improvement. Under these circumstances, the specifications of the drug substance and drug product may be revised accordingly during Phase 1 trial, provided that these changes can be justified scientifically with supporting data.

14.2.2 CMC Submissions After Initial Phase 1 Study

Any new CMC information generated after the initial IND submission is required to be submitted as an information amendment as per 21 CFR part 312.31 to ensure the identity, strength, potency, quality, and purity of the drug used in the clinical trials. As per FDA (2003a) guidance for INDs for phase 2 and phase 3 studies, any CMC modifications that are critical to ensure the safe use of the test article should be submitted through information amendments before any clinical studies start.

Regarding the manufacture of drug substance, generally the sponsor should provide more detailed information on process description, establishment of critical steps, control of intermediates, and final drug substance (FDA 2003a). Changes in the manufacturing process that may affect safety should be highlighted. As the drug-development program progresses, physical properties linked to the performance of the drug product should be well characterized and should be included in the drug substance specifications, and submitted to the IND with the data. As more

knowledge is gained and batch analysis, toxicology studies results, and stability data become available, the control of drug substance (specifications) may be refined. The sponsor should report any changes in the specifications to the IND in an amendment. Validation data for the analytical methods that are not from the official references (e.g., United States Pharmacopeia (USP)) should be available and be submitted upon request. Because of major safety concern, new impurities should be qualified and reported in the information amendment. In addition, stability data from an earlier phase study should be submitted. Description of the stability program (and any changes thereafter) supporting the clinical studies should be submitted, including tests, acceptance criteria, analytical procedures, time points, storage conditions, and the duration of the study. Generally, as the development program moves to a later stage and larger-scale clinical trials, more detailed information on the drug substance will be needed, including, but not limited to, the manufacturing process, characterization, control of starting materials, critical steps and intermediates, as well as the final drug substance and its stability.

Regarding the manufacture of the drug product, information amendments supporting phase 2 and phase 3 studies should update any changes from the previous submission (FDA 2003a). This includes components and composition of the formulation, manufacturers, manufacturing process and controls, control of excipients and drug product, container closure system (packaging), and stability. Any changes in the drug product specifications, such as adding or deleting specification items, relaxing acceptance criteria, should be reported with justification and supportive data. At this stage, the dissolution method (FDA 1997a) should usually be developed, finalized, and validated, as appropriate. Ideally, the dissolution method should be discriminatory to detect any significant changes in the critical product quality attributes caused by any major manufacturing deviations. A well-designed dissolution method may help establish *in vivo*–*in vitro* correlation (IVIVC) if the sponsor plans for that route (FDA 1997b). With successful validation, the dissolution method may also possibly be used as a key parameter to link between the drug product batches used for bioequivalence (BE) studies, clinical trials, and to-be-marketed formulations (FDA 2003b). Similar to drug substance, stability program for the drug product development should be submitted and any changes be reported. Stress tests on both the drug substance and drug product should be carried out to investigate the potential degradation pathway as well as validate the analytical procedures (FDA 2003a).

During the development of a poorly water-soluble drug substance for oral administration, in order to improve the bioavailability, it almost becomes the routine strategy for the pharmaceutical industry to take one of the following approaches, which have been covered from the technology perspective in the previous chapters of this book.

- (a) Selection of an appropriate solid form of the drug substance for formulation development. This route usually involves a comprehensive salt/cocrystal/poly-morph screening (Brittain 2009; Flinn et al. 2008; Stahl and Sutter 2006). Based on the screening results, the solid forms that have satisfactory physicochemical properties (such as aqueous solubility, hygroscopicity, stability, etc.) are further

investigated and evaluated for formulation development, and tested for improved bioavailability. After the final decision is made regarding which solid form is to be used for product development to support clinical studies, a full characterization and continuous understanding of this form will carry through the whole drug development. Properties of the solid form that are critical to the product quality, safety, and efficacy should be built into the control strategies. For example, if a metastable form of a drug substance is used in a solid oral dosage form rather than a stable crystalline form, it is appropriate to characterize the drug product to ensure that there is no phase transition induced during manufacturing and/or storage (Gift et al. 2009). The stability of the meta-stable polymorph in the drug product can be assured by the long-term stability studies, and appropriate regulatory control on the solid form should be established based on these results (ICH Q6A 1999).

- (b) Control of the drug substance particle size. Due to the poor aqueous solubility of the drug substance, its absorption/bioavailability may be far from expectation to achieve the desired therapeutic effect. However, the bioavailability of a poorly soluble drug substance may be greatly enhanced by reducing the particle size to micron- or nano-level to increase the surface area and therefore faster dissolution (Hu et al. 2004; Merisko-Liversidge et al. 2003). If particle-size reduction is the selected route for formulation development for clinical trials and future commercial drug product, the challenge would be to define the particle-size range and link it to the desired exposure. In addition, experimental data can be collected to demonstrate that the particle size of the drug substance does not change significantly during routine manufacturing and during long-term storage within the proposed retest period. For this purpose, appropriate regulatory specification(s) (e.g., particle-size distribution and specific surface area) should be developed and established based on sufficient data (ICH Q6A 1999).
- (c) Lipid formulation (Cuine 2009; Porter et al. 2008; Pouton 2006). This is being used as a broad definition in the context of covering use of any lipid, surfactant, or cosolvent to solubilize the drug substance for oral formulation development, for example, Self-Emulsifying Drug Delivery System (SEDDS) (Tang et al. 2008). In this case, the drug substance is completely dissolved in the formulation vehicle and the solution is then filled in capsules. Due to the solution state of the poorly soluble drug substance in the vehicle, it is desirable to characterize the formulation system, which includes, but not limited to, the solubility of the drug substance in the vehicle at a relevant temperature range, potential precipitation/crystallization because of supersaturation, chemical stability, etc. Under ambient temperature conditions, the formulation solution could be in a liquid, semi-solid, or solid state, depending on the composition of the vehicle as well as drug loading.
- (d) Amorphous solid dispersion prepared through various technologies. This includes most of the amorphous formulation development involving pharmaceutical technologies such as hot-melt extrusion, spray drying, drug-carrier coprecipitation, and bead layering (Lakshman et al. 2008; Serajuddin 1999). The physical stability (and possibly, the chemical stability depending on the technology being used) of

the drug product is the primary concern for this approach. Again, the desired stability profiles of the drug product can be supported by characterization and understanding of the amorphous system. It is recommended to use scientifically sound strategy for the screening of the dispersion carrier, selection of a plasticizer, as well as technology for the manufacturing process. With the data collected during formulation development using this approach, the critical process parameters and their operation conditions can be finalized and justified.

The above four approaches are the most commonly used strategies for the formulation development of poorly water-soluble drugs. These four approaches are far from a complete list of approaches used for this type of drugs. Throughout the clinical studies, sufficient controls should always be in place to ensure the safety of the subjects. In the late-stage pivotal clinical trials to support the efficacy claim of the drug product, additional or more stringent controls are strongly recommended to ensure the consistent product quality as well as satisfactory performance of the drug product. For instance, it is a good idea to monitor the solid-form stability of the drug substance in the drug product by powder X-ray diffraction/FT-Raman and by dissolution when a meta-stable form is used in the drug product, so that the exposure of the drug is not reduced due to the potential phase transition, and therefore, the efficacy of the drug product is not affected.

14.3 New Drug Application (NDA) Stage

21 CFR part 314 regulates NDAs for commercialization. Specifically, 21 CFR 314.50(d)(1) covers the requirements for CMC submission in an NDA application. Compared with the requirements in an IND, the CMC section in an NDA application should be a complete package including every aspect of the CMC of the drug substance and drug product containing data and information in sufficient details to ensure the identification, strength, quality, and purity of both the drug substance and the drug product, as well as potency and bioavailability of the drug product. The following contents of this chapter focus on the general requirements for the CMC section of the NDA as well as a few examples from the currently approved drug products of poorly water-soluble compounds for oral administration.

14.3.1 Drug Substance

Information required for the drug substance in the NDA is more detailed and comprehensive as compared to that required for an IND (21 CFR 314.50(d)(1)(i)). The following information should be submitted in the NDA.

- (a) "A full description of the physical and chemical characteristics and stability." As explained in the relevant guidance (FDA 1987a), the physical and chemical

characteristics include parameters for the description (appearance, color, odor, etc.) of a compound, chemical name (including established name), Chemical Abstracts Service (CAS) number, molecular formula and molecular weight, stereochemistry, solubility profile (pH-solubility profiles as well as solubility in various solvents), logP, pKa, melting point, polymorphism, etc. The chemical structure of the drug substance should be elucidated and confirmed using appropriate methodologies. Examples include UV spectroscopy, FTIR, single-crystal X-ray crystallography, NMR (proton and ^{13}C solid state), mass spectrometry, and elemental analysis.

The stability characterization for the drug substance is usually carried out as per ICH Q1A(R2) (2003a) and Q1B (1996). Generally, stability data for three primary batches at a minimum of at least pilot scale by the same synthetic route and manufacturing procedures as the final commercial process should be submitted for the purpose of NDA submission, with the drug substance tested at both long-term (minimum 12 months) and accelerated storage conditions (6 months) (ICH Q1A(R2) 2003a). Depending on the proposed storage conditions for the drug substance, the long-term and accelerated conditions for stability testing are adjusted accordingly. For drug substance intended for storage under ambient conditions, $25^{\circ}\text{C} \pm 2^{\circ}\text{C}/60\% \pm 5\%$ RH is generally used as the long-term storage condition and $30^{\circ}\text{C} \pm 2^{\circ}\text{C}/65\% \pm 5\%$ RH may be included as the intermediate condition in case any significant change occurs within 6 months under accelerated conditions ($40^{\circ}\text{C} \pm 2^{\circ}\text{C}/75\% \pm 5\%$ RH). If the drug substance is proposed to be stored in a refrigerator, the long-term and accelerated storage conditions are $5^{\circ}\text{C} \pm 3^{\circ}\text{C}$ and $25^{\circ}\text{C} \pm 2^{\circ}\text{C}/60\% \pm 5\%$, respectively. For a drug substance proposed to be stored in a freezer, $-20^{\circ}\text{C} \pm 5^{\circ}\text{C}$ should be used as the long-term conditions. Under this situation, ICH Q1A(R2) (2003a) does not specify the accelerated storage condition; however, it recommends to test a single batch of drug substance at an elevated temperature (e.g., $5^{\circ}\text{C} \pm 3^{\circ}\text{C}$ or $25^{\circ}\text{C} \pm 2^{\circ}\text{C}$) to address the short-term temperature excursions outside the proposed long-term storage condition under $-20^{\circ}\text{C} \pm 5^{\circ}\text{C}$. The evaluation and analysis of the stability data generated under both long-term and accelerated conditions to establish the retest period of the drug substance usually follow ICH Q1E (2003b). Depending on the stability of the drug substance under the storage conditions tested, different scenarios for predicting its retest period are used, which are summarized in the decision tree (Fig. 14.1) in ICH Q1E (2003b).

- (b) “the name and address of its manufacturers.” The applicant should provide the establishment registration number, the address of the drug substance manufacturer(s), applicable Drug Master File (DMF) number, as well as contact and telephone number. The address should be that of the manufacturing, packaging and controls (release as well as stability testing) facilities, including contract facility(ies) used for this purpose (FDA 1987a).
- (c) “the method of synthesis (or isolation) and purification of the drug substance.” This part of the submission should include definition and control procedures of the regulatory starting material; reagents, solvents, and auxiliary materials

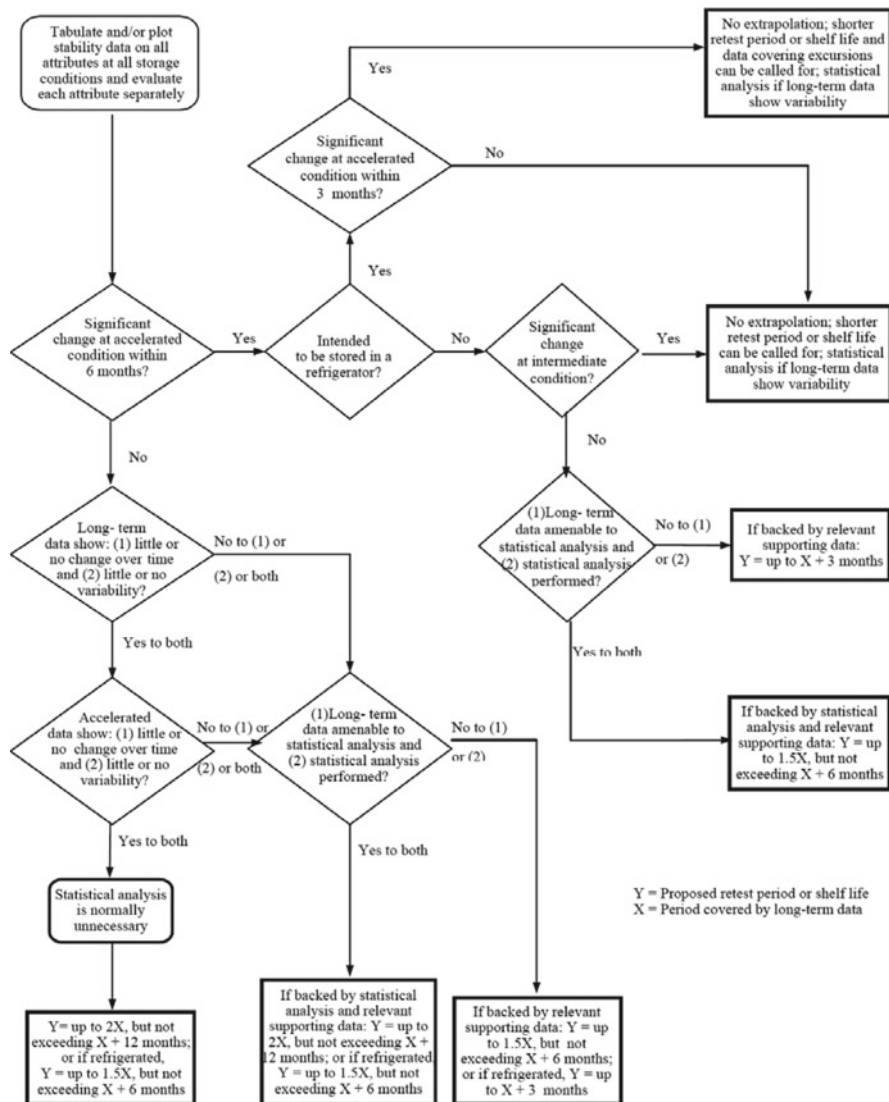

Fig. 14.1 Decision tree for stability data evaluation for establishing retest period of a drug substance or expiry of a drug product (frozen products not included)

controls; description of the synthesis by flowchart and written statement of steps; and purification (FDA 1987a). For a drug substance produced by chemical synthesis, both FDA guidance (1987a) and ICH Q7 (2000) indicate that a starting material should be a significant structural fragment of the drug substance, with defined chemical properties and structure. The starting materials

should have adequate controls, which include tests, analytical procedures, and acceptance criteria. Similarly, the reagents, solvents, and auxiliary materials should have specifications. The description of the synthetic process should include the details, such as typical equipment, solvents, catalyst and reagents, reaction conditions, in-process tests for reaction completion, isolation and purification procedures, etc.

- (d) “the process controls used during manufacture and packaging.” With the experience and knowledge gained during the IND stage, the applicant should establish in-process controls to monitor the critical reaction steps and intermediates (FDA 1987a). These controls are generally developed and justified to ensure the conditions and completion of reaction, to confirm identification and purity of the isolated intermediate(s), or to determine a critical physicochemical parameter. The tests, acceptance criteria, and the analytical procedures should be submitted with justification for the acceptance criteria.
- (e) “the specifications necessary to ensure the identity, strength, quality, and purity of the drug substance and the bioavailability of the drug products made from the drug substance, including, for example, tests, analytical procedures, and acceptance criteria relating to stability, sterility, particle size, and crystalline form.” The applicant should provide specifications for the release and stability testing to support the retest period (also referred as shelf life), detailed description of analytical procedures and their validation reports where needed (FDA 1987a; FDA 2000a). ICH Q6A (1999) provides guidance for establishing and justifying specifications for a new drug substance. Briefly, the following items are generally included in the drug substance specifications: description, identification, assay, and impurities. Description is usually a qualitative statement on the color, odor, and state of the drug substance. Identification tests should be specific to the drug substance so that the drug substance can be differentiated from structurally similar and related compounds. ICH Q6A (1999) recommends two identification tests with different principles or a combination of tests into one procedure. The assay test is used to determine the content of a drug substance, with the specification typically set within 98%–102%, or otherwise justified with sufficient supporting data. The impurity profile of a drug substance includes organic (starting materials, intermediates, by-products, and degradants), inorganic (heavy metals, catalysts), and residual solvents. ICH Q3A(R2) (2006a) provides detailed information for reporting, identification, and qualification of organic impurities in the drug substance. Also, ICH Q3C(R5) (2011a) provides detailed information on reporting and control strategies for residual solvents. Official compendial analytical procedures (such as USP) may be adopted if applicable. If non-official test methods are used, which may be the most likely case for a new drug substance for assay and organic impurities testing, the analytical procedures should be validated against specified criteria, as described in the FDA (2000a) and ICH Q2(R1) (2005) guidances. As certain physicochemical properties of the drug substance may significantly affect the bioavailability of the drug product, particularly for poorly water-soluble drugs, specification for items such as crystal form, particle size distribution, or surface area may be needed (ICH

Q6A 1999). The acceptance limits should be proposed and justified based on batch analysis data, qualification through toxicological studies, drug products used in pivotal clinical studies.

14.3.2 Drug Product

Similar to drug substance, the information required for the drug product in the NDA is described in 21 CFR 314.50(d)(1)(ii), which is a complete compilation of information and data collected for the to-be-marketed drug product, more detailed and comprehensive as compared to that required for an IND. The following information is required to be submitted in the NDA.

- (a) “A list of all components used in the manufacture of the drug product (regardless of whether they appear in the drug product) and a statement of the composition of the drug Product.” All the components used in the manufacturing of the drug product should be included and their grades be clearly stated. In addition, the quantitative composition of a unit dose of the drug product should be provided by the weight of the drug substance and the excipients (usually the percentage is also provided). The representative batch formulation for each dose strength should be provided in the submission (FDA 1987b).
- (b) “the specifications for each component.” The specifications for the excipients, including those removed during the manufacturing process, should be provided in the submission (FDA 1987b). For novel excipients that are used for the first time in the drug product, full details of their manufacture, characterization, and controls, with cross-references to supporting safety data (nonclinical and clinical), should be provided (FDA 2001). This information may be included in the NDA submission or in a DMF (FDA 1989).
- (c) “the name and address of each manufacturer of the drug product.” The name and address (including building number if applicable) of all the facilities (including contract manufacturing/testing facilities) that are involved in the manufacturing, packaging, testing (release and stability) of the drug substance and the finished drug product should be provided. The name and address of the suppliers of the novel or critical excipients may be needed in the application (FDA 1987b).
- (d) “a description of the manufacturing and packaging procedures and in-process controls for the drug product.” A copy of the proposed or actual master production batch record for the manufacture of the commercial lot of drug product or a comparably detailed description of the production process for a representative batch of the drug product is required (21 CFR 314.50(d)(1)(ii)(c)). A flowchart and a step-by-step description of the manufacturing process are provided in the submission. In both situations, the equipment, operating conditions, and sampling points for in-process controls are usually included (FDA 1987b). In-process controls are usually established and justified based on appropriate data generation and analysis during development and process validation. The tests, acceptance criteria/ranges, and the description of the in-process

analytical method should be provided for the in-process controls for commercial drug product manufacture (FDA 1987b).

- (e) “the specifications necessary to ensure the identity, strength, quality, purity, potency, and bioavailability of the drug product, including, for example, tests, analytical procedures, and acceptance criteria relating to sterility, dissolution rate, container closure systems.” Specifications should be established to ensure the batch-to-batch quality and hence the safety and efficacy of the drug product. ICH Q6A (1999) provides detailed guidance on the establishment of specifications. The universal tests that are generally applicable to all drug products are description, identification, assay, and impurities, which are similar to that for the drug substance. Also similar to the drug substance, ICH Q3B(R2) (2006a) covers the rationale for reporting organic impurities (e.g., degradation products) in the drug product. The specifications for degradation products are usually established based on the available stability data, the proposed shelf life, and storage conditions, and daily dose of the drug product. However, the acceptance limits should always be within the levels qualified in the toxicology studies. For a genotoxic impurity, FDA (2008) guidance recommends a maximum daily intake of 1.5 µg.

In addition to the universal tests, additional specific tests may also be established depending on the dosage form and administration route. For the solid oral dosage forms (e.g., tablets and capsules), additional specific tests may include dissolution, disintegration, hardness, content uniformity, water content, microbial limits, etc. (ICH Q6A 1999). Similarly, for the liquid oral formulation (e.g., solution and suspension), additional specific tests may include uniformity of dosage unit, pH, microbial limits, assay of preservative, dissolution, particle-size distribution, redispersibility, etc. (ICH Q6A 1999). The dissolution method development report is usually provided in the NDA application, which supports and justifies the dissolution conditions selected. Dissolution specification is usually established based on the dissolution characteristics of the batches used in pivotal clinical trials and/or in confirmatory bioavailability studies (FDA 1997a and 1997b). Depending on the solubility and rate of dissolution, one - text looks like (one-,), two, or multi-point dissolution test specification may be established using USP Type 1 or Type 2 Apparatus. Standard tests, such as disintegration, content uniformity, and microbial limits, can be referenced to the respective official USP methods and acceptance criteria, unless modification is necessary as justified scientifically (USP 33-NF 28 2011).

If an analytical method for the drug product is not referenced to official sources (e.g., USP), the submission is required to include description of the analytical procedures and method validation report.

- (f) “Stability data with proposed expiration dating.” ICH Q1A(R2) (2003a) recommends stability data from at least three primary batches of the drug product, with two batches minimally at pilot scale and the third batch may be smaller with sufficient justification. These primary batches should be representative of the commercial manufacturing process. The stability study should be conducted in the commercial container closure system under the proposed long-term and accelerated storage conditions. Similar to the drug substance, ICH Q1A(R2)

(2003a) recommends that stability data of at least 12 months under long-term and 6 months under accelerated storage conditions be submitted at NDA filing. The long-term and accelerated storage conditions used for stability studies also depend on the proposed storage conditions of the drug product as well as the container closure system. In most cases, where the drug product is proposed to be stored under ambient conditions, the long-term storage condition is $25^{\circ}\text{C} \pm 2^{\circ}\text{C}/60\% \pm 5\% \text{ RH}$ or $30^{\circ}\text{C} \pm 2^{\circ}\text{C}/65\% \pm 5\% \text{ RH}$, and the accelerated storage condition is $40^{\circ}\text{C} \pm 2^{\circ}\text{C}/75\% \pm 5\% \text{ RH}$. It is strongly recommended that aqueous-based products packaged in semi-permeable containers be evaluated for potential water loss during storage (ICH Q1A(R2) 2003a). The stability data of the drug product from both long-term and accelerated storage conditions are evaluated to predict the shelf-life of the drug product (ICH Q1E (2003b)), as summarized in the flowchart in Fig. 14.1 in this chapter.

Reference to the current edition of the U.S. Pharmacopeia and National Formulary may satisfy relevant requirements for drug substance (21 CFR 314.50(d)(1)(i)) and drug product (21 CFR 314.50(d)(1)(ii)(a)).

The above information on the general filing requirements of the CMC section in an NDA submission is far from complete, since there are additional filing requirements such as environmental assessment (21 CFR 314.50(d)(1)(iii)), relevant CMC sections in the labeling (package insert, carton and immediate container labels), which are not discussed in this chapter. The brief summary of the NDA filing for poorly water-soluble compounds is based on the authors' understanding of the current FDA regulations and available guidance to the pharmaceutical scientists. If detailed guidance is needed for certain specific aspects of an NDA application, it is strongly recommended to refer to the relevant guidelines on ICH (2011b) guidances and/or FDA (2011a and 2011b) guidances.

14.3.3 Case Studies of Approved Drug Products for the Poorly Soluble Drugs

The formulation development and commercialization of poorly water-soluble compounds for oral delivery involves various approaches and strategies to improve their in vivo exposure, as discussed in Sect. 14.2.2. Poorly water-soluble drugs that have been approved and commercialized have their own characteristics and technical difficulties arising from the poor solubility, which have been successfully addressed. However, they all may have common challenges from the regulatory perspective. The following are a few examples of the approved drug products.

14.3.3.1 Solid-Form Selection: Carbamazepine

Carbamazepine ([298-46-4], 5H-dibenz[b,f]azepine-5-carboxamide, Fig. 14.2) is currently approved for the indication of epilepsy and trigeminal neuralgia. It is practically

Fig. 14.2 Molecular structure of carbamazepine

insoluble in water, but soluble in organic solvents such as alcohol, acetone, and propylene glycol (O'Neil 2006). Four anhydrous polymorphs (forms I–IV) and a dihydrate of Carbamazepine have been reported and investigated widely (Lang et al. 2002; Rustichelli et al. 2000). It has been shown that the anhydrous polymorphs convert to the dihydrate in an aqueous medium (Lehto et al. 2009; Tian et al. 2006). In vivo pharmacokinetic data of carbamazepine in dogs (Kobayashi et al. 2000) have shown that the solid form is a critical factor for bioavailability. The commercial carbamazepine drug substance is anhydrous form III (or the β form) as specified in the USP monograph. However, due to the phase conversion of form III to the dihydrate, bioequivalence was observed in the 200 mg carbamazepine tablets almost two decades ago (Meyer et al. 1992). Therefore, from scientific and regulatory perspective (ICH Q6A 1999), it is desirable to control the phase purity and establish specifications for both the drug substance (e.g., powder X-ray diffraction, particle size, FTIR) and the drug product (e.g., dissolution test, powder X-ray diffraction) to ensure the in vivo performance of the drug product.

For a new drug substance, the potential polymorphism (including hydrates and solvates) should be explored and investigated to avoid any future surprises (Bauer et al. 2001; Dunitz and Bernstein 1995; FDA 1987a; ICH Q6A 1999). Thermodynamic characterization is usually carried out on the solid crystalline forms that can be produced in bulk and are relatively stable under ambient conditions, as in the case of carbamazepine, the anhydrous polymorphs, and the dihydrate. Ideally, the phase transition kinetics from the metastable to the stable form can be also characterized using the pure phases with the parameters such as temperature, water activity (relative humidity), particle size, etc. In addition, if the metastable form is chosen for formulation development, the manufacturing process (e.g., wet granulation and tablet compaction) that may induce phase change requires characterization as well to ensure minimal or absence of phase conversion to the undesired solid form (Gift et al. 2009). Thereafter, the stability of the selected crystal form can be further monitored and confirmed during the drug product stability studies in the proposed commercial packaging configuration by testing against the established specifications (e.g., dissolution) and examining for any potential trend of change. Failure to meet these specifications or detection of a significant trend of change due to phase transition would alert the formulation scientists to modify the formulation composition, manufacturing process, or the container closure system.

ICH Q6A (1999) decision tree#4 (Fig. 14.3) provides the criteria for the establishment of a specification for polymorphism in drug substances and drug products. Briefly, if the polymorphs of a drug substance have different physicochemical properties which affect the safety and efficacy of the drug, it is recommended to

Drug Substance

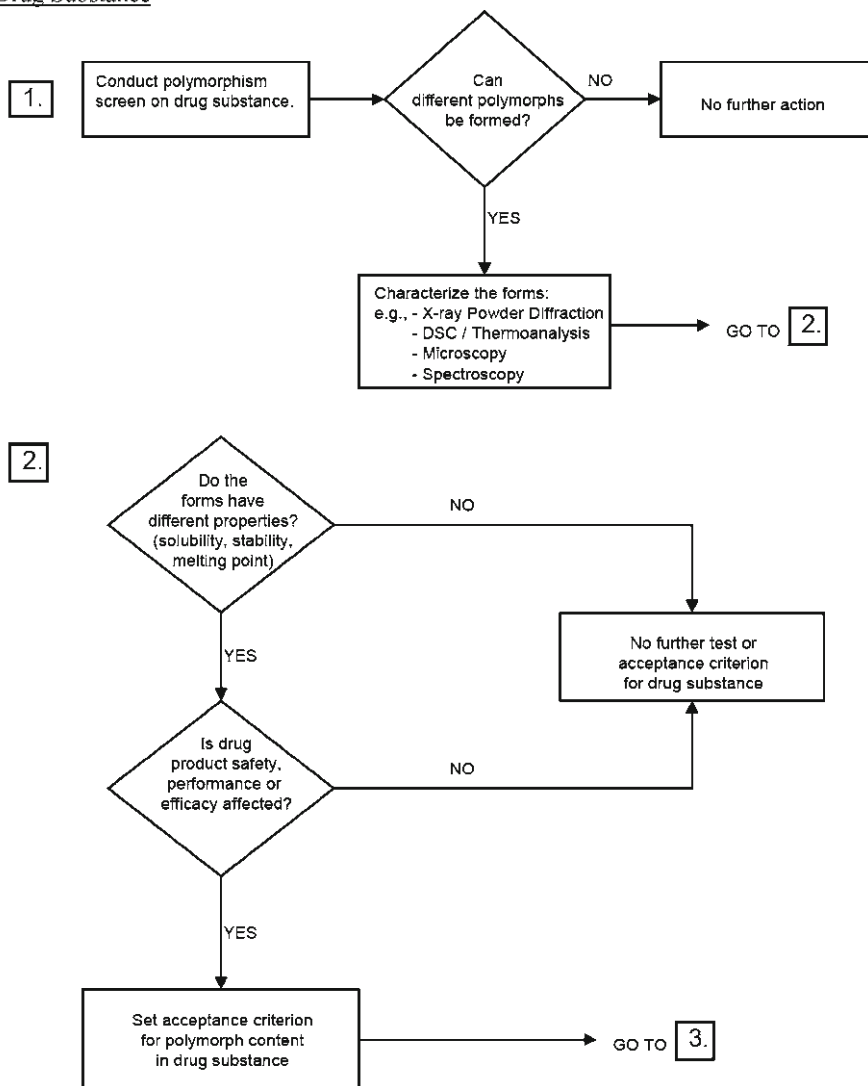

Fig. 14.3 ICH Q6A Decision Tree#4 for setting up specifications on polymorphism

establish specification on the polymorphic form. If adequate control and test (e.g., dissolution) have been established to detect any changes in the content of the specified polymorphic form in the drug product, typically no further action is needed. If a phase conversion occurs, which affects the safety and efficacy of the drug product, and there is no established control in place to monitor the change, then a specification for the polymorphic form should be established.

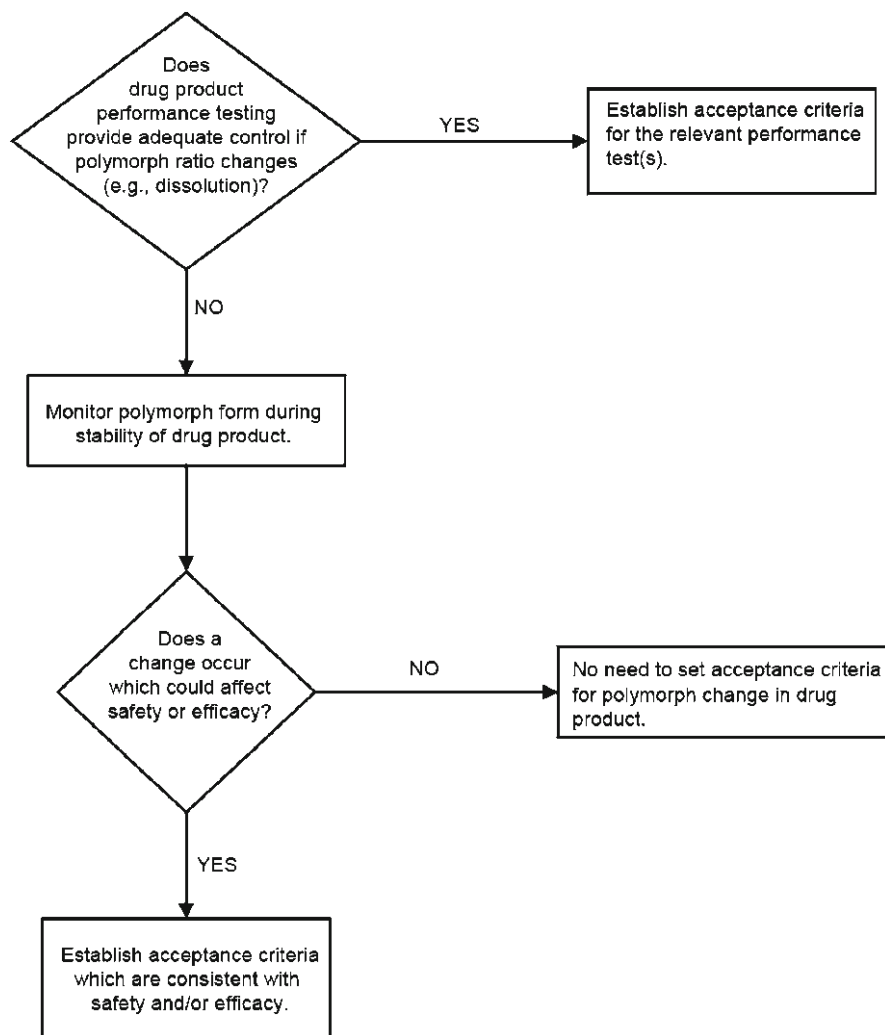

Fig. 14.3 (continued)

14.3.3.2 Particle-Size Reduction: Fenofibrate (Tricor[®] Tablet) and Sirolimus (Rapamune[®] Tablet)

Fenofibrate ([49562-28-9], isopropyl 2-[*p*-(*p*-chlorobenzoyl)phenoxy]-2-methylpropanoate, Fig. 14.4) is approved for the adjunctive therapy to diet for hypercholesterolemia and hypertriglyceridemia. It is practically insoluble in water, slightly soluble in methanol and ethanol, soluble in acetone, ether, benzene, and chloroform, and very soluble in methylene chloride (O'Neil 2006). Fenofibrate is currently marketed under several brand names (Triglide, Fenoglide, Tricor, Antara, Lipofen, and Trilipix) and also as generic drug products (Orange Book 2011).

Fig. 14.4 Molecular structures of fenofibrate (*left*) and sirolimus (*right*)

Sirolimus ([53123-88-9], also known as rapamycin, (3*S*,6*R*,7*E*,9*R*,10*R*,12*R*,14*S*,15*E*,17*E*,19*E*,21*S*,23*S*,26*R*,27*R*,34*aS*)9,10,12,13,14,21,22,23,24,25,26,27,32,33,34,34*a*-hexadecahydro-9,27-dihydroxy-3-[(1*R*)-2-[(1*S*,3*R*,4*R*)-4-hydroxy-3-methoxycyclohexyl]-1-methylethyl]-10,21-dimethoxy-6,8,12,14,20,26-hexamethyl-23,27-epoxy-3*H*-pyrido[2,1-*c*][1,4]oxaazacyclohentriacontine-1,5,11,28,29 (4*H*,6*H*,31*H*)-pentone, Fig. 14.4), is a triene macrolide antibiotic isolated from *streptomyces hygroscopicus*, and it is currently approved for the indication of prophylaxis of organ rejection in patients aged ≥ 13 years receiving renal transplants. The currently approved drug products are Rapamune[®] oral solution (1 mg/mL) and tablets (0.5 mg, 1 mg, and 2 mg) (Orange Book 2011). Sirolimus is insoluble in water, but freely soluble in benzyl alcohol, chloroform, acetone, and acetonitrile (O'Neil 2006).

Literature (Bawa 2009) indicates that the Tricor[®] tablets (fenofibric acid eq. 45 and 135 mg strengths) and Rapamune[®] tablets (sirolimus 0.5, 1, and 2 mg strengths) utilized nanotechnology during formulation development for improved bioavailability. Orange Book (2011) lists, three patents relating to nanotechnology for the Tricor[®] tablets, US Patent 6,375,986 (Ryde and Ruddy 2000), US Patent 7,276,249 (Ryde et al. 2003a), and US Patent 7,320,802 (Ryde et al. 2003b). Both patents 7,276,249 and 7,320,802 cover the nano particle technology of fenofibrate which is stated to eliminate the food effect upon oral administration and claims for an effective average particle size of less than 2,000 nm. Similarly, US Patent 5,145,684 (Liversidge et al. 1991) is identified to cover the nanotechnology for Rapamune[®] tablets, where an average effective particle size of less than 400 nm is claimed and preparation method, grinding media, as well as dispersion media are included.

As recommended by ICH Q6A (1999), adequate control on particle-size distribution of the drug substance should be established for the drug product developed via particle-size reduction when particle size is a critical factor for bioavailability, and particle-size distribution should be included as part of the drug substance specifications. From a scientific and regulatory perspective (ICH Q1A(R2) 2003a), when particle size reduction is carried out in the drug substance, through either dry milling

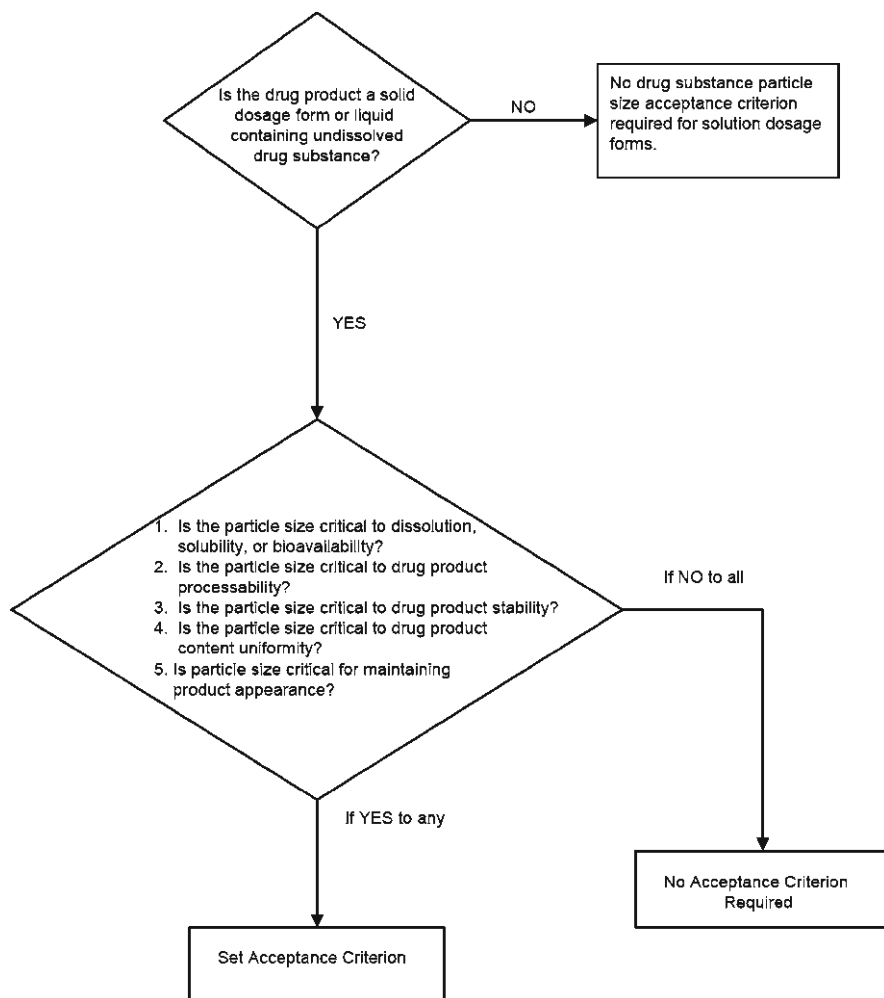

Fig. 14.5 ICH Q6A Decision Tree#3 for setting up specifications on drug substance particle-size distribution

(e.g., jet mill) or wet milling, sufficient stability data are desirable to demonstrate that there is no significant change in the particle size of the milled drug substance throughout the proposed retest period (as a final drug substance) or storage period (as an intermediate during drug product manufacturing for a wet-milled suspension). In addition, it is desirable to have proper controls (e.g., dissolution) in place for the final drug product to monitor any potential change in the particle size of the drug substance throughout the proposed expiry so that the safety and efficacy of the drug product is not affected ICH Q6A (1999).

ICH Q6A (1999) decision tree#3 (Fig. 14.5) provides guidance on setting acceptance criteria for drug substance particle-size distribution. As per the decision tree,

Fig. 14.6 Molecular structure of ritonavir

a specification for particle size distribution is necessary for essentially all poorly water-soluble drugs and for all solid dosage forms (e.g., tablet and capsule) as well as suspension for oral administration.

14.3.3.3 Lipid Formulation: Ritonavir (Norvir[®] Capsule) and Sirolimus (Rapamune[®] Oral Solution)

Ritonavir ([155213-67-5], 5*S*-(5*R**,8*R**,10*R**,11*R**)10-hydroxy-2-methyl-5-(1-methylethyl)-1-(2-(1-methylethyl)-4-thiazolyl)-3,6-dioxo-8,11-bis(phenylmethyl)-2,4,7,12-tetraazatridecan-13-oic acid, 5-thiazolylmethyl ester, Fig. 14.6) is a human immunodeficiency virus (HIV) protease inhibitor indicated in combination with other antiretroviral agents for the treatment of HIV infection. Crystalline ritonavir is practically insoluble in aqueous media with a solubility of 400 µg/mL in 0.1N HCl and 1 µg/mL in pH 6.8 phosphate buffer at 37°C (Law et al. 2004). As per the Orange Book (2011), the currently approved drug products containing ritonavir are Norvir[®] Oral Solution (80 mg/mL), Norvir[®] Capsule (100 mg) and Norvir[®] Tablet (100 mg), Kaletra[®] Oral Solution (80 mg/mL lopinavir and 20 mg/mL ritonavir), Kaletra[®] Capsule (133.3 mg lopinavir and 33.3 mg ritonavir), and Kaletra[®] Tablet (200 mg lopinavir and 50 mg ritonavir; 100 mg lopinavir and 25 mg ritonavir). A well-known case is the currently approved Norvir[®] 100 mg strength capsule, which has to be reformulated due to the precipitation of ritonavir polymorph II in the originally approved soft gelatin capsule (Chemburkar et al. 2000).

The currently approved labeling for Norvir[®] (2010) indicates that the reformulated soft gelatin capsule has the following inactive ingredients: butylated hydroxytoluene, ethanol, gelatin, iron oxide, oleic acid, polyoxyl 35 castor oil, and titanium dioxide. Based on the formulation components, it appears that the drug product uses an SEDDS formulation with oleic acid for the oil phase, polyoxyl 35 castor oil as an emulsifier, and butylated hydroxytoluene as an antioxidant to prevent the peroxidation of oleic acid. As indicated in the Orange Book (2011), the formulation composition appears to be claimed in US Patent 6,232,333 (Lipari et al. 1997).

As mentioned previously, in addition to the tablet dosage form, sirolimus is also marketed as Rapamune[®] Oral Solution (1 mg/mL). The currently approved prescribing information for Rapamune[®] Oral Solution (2010) indicates that the drug

Fig. 14.7 Molecular structure of etravirine

product contains the following inactive ingredients: Phosal® 50 PG (phosphatidylcholine, propylene glycol, mono- and di-glycerides, ethanol, soy fatty acids, and ascorbyl palmitate) and polysorbate 80. It appears that sirolimus is solubilized as a solution in the lipid for oral administration, which is covered by US Patent 5,536,729 (Waranis and Leonard 1994; Orange Book 2011).

The scientific and regulatory perspective of the lipid type of formulation may involve establishing appropriate specifications to ensure both physical and chemical stability of the drug product. Physical stability concerns such as crystallization of the drug substance from drug product solution may be addressed by the inspection of appearance of the oral solution or the contents in the capsule. The phase transformation of the drug substance and lipid excipients may be monitored by dissolution testing. Concerns on the chemical stability of the drug product can be addressed by establishing appropriate stability specifications of the drug product. In addition to the concern related to the drug substance stability in the formulation, lipid excipients may also have potential stability issues, such as peroxidation and hydrolysis (Canon 2008; Radomska-Soukharev and Mueller 2006; Radomska-Soukharev 2007). To prevent peroxidation of certain lipid excipients, antioxidant(s) can be used in the formulation. In that case, in the authors' opinion, it may be desirable to establish a specification for the antioxidant content. In addition, depending on the type of lipid used, it may be desirable to store the drug product with protection from light. Additional specifications may also be desirable to control the hydrolysis of some lipid excipients, based on the investigation results of the individual case. The necessity of these controls is a scientific and regulatory decision based on available literature information and/or research conducted by the applicant.

14.3.3.4 Solid Dispersion: Etravirine (Intelence® Tablet) and Ritonavir (Norvir® Tablet)

Etravirine ([269055-15-4], 4-[[6-amino-5-bromo-2-[(4-cyanophenyl)amino]-4-pyrimidinyl]oxy]-3,5-dimethylbenzonitrile, Fig. 14.7) is a second-generation non-nucleoside reverse transcriptase inhibitor indicated for HIV infection. It is practically insoluble in water with less than 1 µg/mL solubility in both water and 0.1 N HCl with a logP > 5 (Weuts et al. 2011) and appears to be lipophilic. Intelence® tablets with two

dose strengths, 100 mg and 200 mg, are currently approved (Orange Book 2011). Orange Book also lists, US Patent 7,887,845 (Verreck and Baert 2006) for the Intelence tablet formulation, which claims various processes for manufacturing the solid dispersion of etravirine with water-soluble polymers. Specifically, Claim 1 of Patent 7,887,845 covers “a particle comprising a solid dispersion comprising” (a) a defined group of compounds of interest “and (b) one or more pharmaceutically acceptable water-soluble polymers”. The manufacturing processes, as covered in the patent, include spray drying, film casting, or melt extrusion of etravirine with polymers. As described in the currently approved labeling (Intelence® Tablets Full Prescribing Information 2010), hypromellose is the only water-soluble polymer used in the formulation, therefore, it is the primary polymeric carrier in the solid dispersion.

Ritonavir 100 mg tablet (Norvir® Tablet) is another example of solid dispersion formulation of a poorly soluble drug which was recently approved in addition to the previously approved oral solution and softgel capsule formulations (Orange Book 2011). US Patent 7,364,752 (Fort et al. 2000) is listed for the tablet formulation, which covers the hot-melt extrusion process to produce the solid dispersion of ritonavir in a water-soluble polymer.

These approved drug products demonstrate, solid dispersion to be a successful approach for the formulation development of poorly water-soluble drugs. The dispersion may be produced by hot-melt extrusion which is used in the manufacture of Norvir® tablets, or by alternative technologies such as spraying, drying, beads layering, etc. In most cases, the technical challenge for the solid dispersion approach is the selection of suitable excipient(s) as well as appropriate drug loading for the dispersion system to provide satisfactory physical stability to the drug product. To tackle this challenge, the drug–polymer dispersion system should be thoroughly characterized and understood. In the authors’ opinion, to help ensure consistent quality of the drug product, it would be desirable that the drug product specifications include a specification to control the crystallinity of the drug substance in the finished drug product, such as powder X-ray diffraction. To serve the same purpose, dissolution test may also be desirable as an indicator of any change in the crystallinity of the drug product. Due to the plasticizing effect of water in an amorphous system, which facilitates the crystallization of the amorphous drug substance in the product (Tong and Zografi 2004), the water content should also be tightly controlled and the acceptance range be justified based on stability data (ICH Q6A 1999).

14.3.4 Concept of Biopharmaceutics Classification System (BCS) in Developing Poorly Water-Soluble Drugs

The concept of BCS classification was introduced by Amidon et al. (1995) in order to understand the importance of solubility and permeability on drug absorption. Four BCS categories are defined based on the solubility and permeability of a drug: case 1 with high solubility and high permeability; case 2 with low solubility and

high permeability; case 3 with high solubility and low permeability; and case 4 with low solubility and low permeability. The original article provides the theoretical basis for BCS classification using a transport model and analysis of human permeability results for a number of representative drugs.

FDA (2000b) issued a guidance on the waiver of in vivo bioavailability and bioequivalence studies for immediate-release solid oral dosage forms based on BCS classification, which defines the two terms high solubility and high permeability from a regulatory perspective. For an immediate release (IR) drug product, if the highest dose strength is soluble in the aqueous media of 250 mL or less in the pH range of 1–7.5, the drug substance is considered highly soluble. High permeability is defined by the extent of absorption of a drug determined in humans at 90% or higher. As pointed out in the guidance, the extent of absorption is the fraction of dose absorbed, rather than systemic bioavailability.

The initial characterization on the aqueous solubility and permeability of a new chemical compound is generally carried out in the discovery stage, where preliminary information is generated to provide early reading on the BCS classification. With the availability of the compound of better purity as well as final selection on solid form in development stage, preformulation characterization of the drug substance provides more reliable and more accurate aqueous solubility results. Therefore, with the solubility information generated from preformulation studies and the permeability/absorption data derived from human pharmacokinetic studies, in vivo animal models or in vitro methods, it is relatively simple to determine whether a compound is highly soluble and highly permeable as defined in the FDA (2000b) guidance. The reality is, however, in many cases, the drug substances selected for clinical development are very poorly water soluble. Regardless of their BCS classifications (2 or 4), if the pharmaceutical technologies described earlier are used for bioavailability enhancement and final commercial drug product marketing, regulatory approaches similar to those described in the examples may be taken.

14.4 Concluding Remarks

Discovery and development of new drug products, as well as regulatory evaluation of their safety and efficacy before approval for marketing, have always been based on the advancement of science and technology. From the very first steps in drug discovery with disease target identification and validation, identification of the pharmacophore and leads selection, to the later stages in pharmacology/toxicology investigation, preformulation characterization and formulation development, safety and efficacy demonstration in clinical trials, the success of a new drug product is the outcome of the close collaboration among the scientists from various backgrounds and expertise. Regulatory evaluation of a new drug product prior to commercialization is carried out with the scientific criteria outlined in the FDA and ICH guidances, which are accessible to the public and serve as useful resources to the industry. As for the formulation development and commercialization of poorly water-soluble

compounds, if a new technology is used in the drug product manufacturing, the finished drug product should meet the CFR requirements on identity, strength, quality, purity, potency, and bioavailability, as supported by the underlying science.

14.5 Acknowledgement

The authors wish to thank Drs. Richard Lostritto, Christine Moore, and Stephen Moore for critically reviewing the manuscript and insightful discussions during the preparation of this book chapter.
